Gray's Anatomy, 40th Edition

By Susan Standring, PhD, DSc, FKC

A universal landmark in medicine ever since Drs. Henry Gray and H.V. Carter published the first edition in 1858, Gray's Anatomy now celebrates its 150th anniversary!

Book features:

- Completely re-imaged, full-colored art program
- Meticulously enhanced and updated artwork throughout, with 1,800 images now in full color
- More than 120 completely new radiological, CT, MR and other imaging studies

Additional Features

Bibliography: An extended bibliography, compiled over several editions of this text, furnishes an exhaustive library of key articles.
Eponyms: Hundreds of eponyms and their definitions are provided.

Getting started

To start browsing, use the table of contents on the left. Click ++ to expand the contents of a section or chapter. Clicking the chapter or section title itself will take you to that section. Alternatively, search the book using the search function above, or look up a term in the complete index.

PREFACE

The 40th edition of *Gray’s Anatomy* celebrates 150 years of continuous publication of an extraordinary book. Although this edition looks very different from the first edition (see Ruth Richardson’s historical introduction on page xvii), the essential aim of Henry Gray and the illustrator Henry Vandyke Carter, to describe the clinically relevant anatomy of the human body, particularly (but not exclusively) for the practicing surgeon, has not changed over the years. Anatomy may be struggling to retain its foothold in many undergraduate medical curricula, but it is enjoying a renaissance at the postgraduate level. A detailed knowledge of clinical anatomy which would have been undreamed of in the first edition, is now essential for clinicians working in technologically driven fields such as imaging, endoscopic and robotic surgery.

Nine Section Editors (Neil Borley, Pat Collins, Alan Crossman, Michael Gatzoulis, Jeremiah Healy, David Johnson, Vishy Mahadevan, Richard Newell and Caroline Wigley) have worked with me in preparing the 40th edition. They have brought their extensive experience as anatomists, cell biologists and clinicians to the task, and I thank them for their dedication and enthusiastic support. Pat Collins, Jeremiah Healy and Caroline Wigley also worked closely with all members of the editorial team in updating the text and artworks for embryology, imaging and microstructure respectively throughout the book. Harold Ellis has meticulously edited the section on eponyms which is available on the website, and has commented on many of the chapters.

Each Section Editor was assisted by a group of Contributors – experienced anatomists and clinicians (sometimes both) who contributed text and/or artworks and original micrographs. The page proofs were scrutinized by a core team of Reviewers and finally a panel of International Reviewers: their comments have been incorporated into the text and I acknowledge their critical input. Working at this level of detail I have often been impressed by how much anatomy remains controversial or is simply unknown: surgeons, radiologists and embryologists often disagree passionately about structural relationships or developmental processes. Gray’s continues to flag up these uncertainties and to present different perspectives.

As a general rule, the orientation of diagrams and photographs throughout the book has been standardized to show the left side of the body, irrespective of whether a lateral or medial view is presented, and transverse sections are viewed from below to facilitate comparison with clinical images. Clinicopathological examples have been selected where the pathology is either a direct result of, or a consequence of, the anatomy, or where the anatomical features are instrumental in the diagnosis/treatment/management of the condition. All of the pre 39th edition artworks, and the great majority of
the images and micrographs of histological and embryological specimens have been replaced: wherever possible, the photomicrographs illustrate human histology and embryology, and non human sources have been acknowledged in the captions. New artworks have either been generated *de novo* or have been taken from other texts (principally *Sobotta's Atlas of Anatomy, Books 1 and 2* or *Gray's Atlas of Anatomy*), making this the first full-colour edition of *Gray's Anatomy*.

I am often asked why *Gray's Anatomy* does not contain *even more* detailed surgical and radiological anatomy, with further examples of anatomical variants and of laparoscopic and endoscopic anatomy, and why we exclude all but a very few references. The answer is that we would love to do this, and to include some systematic anatomy, but we have reached a point where there is no room for more material in a single volume. Short reference lists are provided at the ends of each chapter to guide further reading, and a list of general texts and references covering material presented in more than one chapter, e.g. the distribution of angiosomes, appears on page xxiv. The Bibliography, which collated all of the references cited in a number of earlier editions 35–38, is retained on the website.

I offer my sincere thanks to the editorial team at Elsevier, initially under the leadership of Inta Ozols and latterly of Madelene Hyde, for their guidance, professionalism, good humour and unfailing support. In particular, I thank Alison Whitehouse, Gavin Smith, Martin Mellor and Louise Cook, for being at the end of a phone or e-mail whenever I needed advice. I am especially grateful to my dear husband, Guy Standring, for his tolerance while he has shared his life with *Gray's Anatomy*, and I dedicate my work in this book to him.

*Susan Standring*

May 2008
ACKNOWLEDGEMENTS

Within individual figure captions, we have acknowledged all figures kindly loaned from other sources. However, we would particularly like to thank the following authors who have generously loaned so many figures from other books published by Elsevier:

Much of the illustration in *Gray's Anatomy* has as its basis the work of illustrators and photographers who contributed towards earlier editions, their figures sometimes being retained almost unchanged though more often being used as the foundation for figures that are new to this edition. The Publishers would like to thank them. For illustration reused from the 39th edition, we particularly thank its photographer Sarah-Jane Smith and the artists listed on page iv.

The Publishers would also like to thank: Anne-Marie Childs BSc, MB ChB, MRCP, FRCPCH, Consultant Paediatric Neurologist, The General infirmary at Leeds; James M McCall BSc, MBBS, MRCP, FRCR, Consultant Radiologist, Chelsea and Westminster Hospital, London, and Romney JE Pope MA, MRCP, FRCR, Consultant Radiologist, Royal Marsden and Chelsea and Westminster Hospitals, London, for their help in preparing material for the new edition.
CONTRIBUTORS

Michael A Adams, BSc, PhD
Reader in Spine Biomechanics, Department of Anatomy, University of Bristol, Bristol, UK

Andrew Amis, PhD, DSc(Eng), FI MechE
Professor of Orthopaedic Biomechanics, Imperial College London, London, UK

Robert H Anderson, BSc, MD, FRCPath
Formerly Professor of Paediatric Cardiac Morphology, Institute of Child Health, University College, London, UK
Professor of Paediatrics, Medical University of South Carolina, Charleston, South Carolina, USA

Tipu Aziz, BSc, MBBS, MD, FRCS, FRCS(SN), DMedSci
Professor of Neurosurgery, University of Oxford, Oxford, UK

Timothy J Beale, MBBS FRCS FRCR
Consultant Radiologist, Royal National Throat Nose and Ear Hospital, London, UK

Sue M Black, OBE, BSc, PhD, DSc, FRSE, Hon FRCPS (Glasg)
Professor, Head of Anatomy and Human Identification, College of Life Sciences, University of Dundee, Dundee, UK

Nikolai Bogduk, BSc (Med), MB BS, PhD, MD, DSc, DipAnat, Dip Pain Med, FAFRM, FAFMM, FFPM(ANZCA)
Professor of Pain Medicine, University of Newcastle, Newcastle, New South Wales, Australia

Peter R Braude, PhD, FRCOG, FMedSci
Professor and Head of Department of Women's Health, King's College London
Honorary Consultant in Reproductive Medicine, Guy's and St Thomas' Foundation Trust, London, UK

Jonathan L Brown, MA, MSc, MD, FRCP, DTMH
Professor and Consultant Physician and Gastroenterologist, Gloucestershire Hospitals NHS Trust, Gloucester, UK

Anthony Bull, BEng, DIC CEng, PhD, FI MechE
Reader in Musculoskeletal Mechanics, Department of Bioengineering, Imperial College London, London, UK
Andrew Bush, MB BS (Hons), MA MD FRCP, FRCPC
Professor of Paediatric Respirology, Department of Paediatric Respiratory Medicine, Imperial College and Royal Brompton Hospital, London, UK

Declan JP Cahill, BSc, MSc, FRCS (Urol)
Consultant Urologist, Department of Urology, Guy's and St Thomas' NHS Trust, London, UK

Cécile Chalouni, PhD
Technical Director and Associate Research Scientist in Cell Biology, Department of Cell Biology, Ludwig Institute for Cancer Research, Yale University School of Medicine, New Haven, CT, USA

Ashish Chandra, FRCPath, DipRCPath (Cyto)
Consultant Histopathologist, Guy's and St. Thomas' Hospital NHS Foundation Trust, London, UK

Roger Chinn, MB BS, MRCP, FRCR
Consultant Radiologist, Department of Radiology, Chelsea and Westminster NHS Foundation Trust, London, UK

Bodo EA Christ, MD, PhD, h.c.
Professor, Director of the Institute of Anatomy and Cell Biology, University of Freiburg, Freiburg, Germany

Alfred Cutner, MD, FRCOG
Consultant Gynaecologist, Department of Obstetrics and Gynaecology, University College London Hospitals, London, UK

Catriona L Davies, MB BS, MRCP, FRCR
Consultant Radiologist, Chelsea and Westminster Hospital, London, UK

Patricia Dolan, BSc, PhD
Reader in Biomechanics, Department of Anatomy, University of Bristol, Bristol, UK

Ronald H Douglas, BSc, PhD
Professor of Visual Science, Department of Optometry and Visual Science, City University, London, UK

Justin A Durham, BDS, MFDS, RCS (Ed), FHEA
Clinical Fellow and Honorary Specialist Registrar in Oral Surgery, School of Dental Sciences, Newcastle University, Newcastle, UK

William C Earnshaw, PhD, FRSE
Professor and Wellcome Trust Principal Research Fellow, Wellcome Trust Centre for Cell Biology, University of Edinburgh, Edinburgh, UK
David M Evans, FRCS
Consultant Hand Surgeon, Clinical Director, The Hand Clinic, Windsor, UK

Paul A Felts, PhD
Senior Lecturer, Centre for Anatomy and Human Identification, University of Dundee, Dundee, UK

Alex Freeman, MSc, MBBS, MD, MRCPath
Consultant Urological Pathologist, University College London Hospitals NHS Foundation Trust, London, UK

David Furness, PhD
Reader in Auditory Neuroscience, MacKay Institute of Communication and Neuroscience, The School of Life Sciences Keele University, Keele, UK

Andrew JT George, MA, PhD, FRCPath, FRSA
Professor of Molecular Immunology, Department of Immunology, Division of Medicine, Faculty of Medicine, Imperial College London, London, UK

Jonathan M Glass, BSc, MB BS, FRCS (Urol)
Urologist, Department of Urology, Guy's and St Thomas' Hospitals, London, UK

Michael Gleeson, MD, FRCS
Consultant Otolaryngologist and Skull Base Surgeon to Guy's, Kings and St. Thomas' Hospitals, London
Professor of Skull Base Surgery, National Hospital for Neurology and Neurosurgery, London
Honorary Skull Base Surgeon to the Great Ormond Street Hospital for Sick Children, London, UK

David JA Goldsmith, MA, FRCP
Consultant Nephrologist, Kidney Unit, Guy's Hospital, London, UK

Anthony Graham, BSc (Hons), PhD
Professor of Developmental Biology, MRC Centre for Developmental Neurobiology and Division of Anatomy and Human Sciences, School of Biomedical and Health Sciences, Guy's Campus, King's College London, London, UK

Paul D Griffiths, MB ChB, PhD, FRCR
Professor of Radiology, Academic Unit of Radiology, Division of Clinical Science, University of Sheffield, Sheffield, UK

Gerald PH Gui, MS, FRCS, FRCS(Ed)
Consultant Surgeon, Academic Surgery (Breast Unit), Royal Marsden NHS Foundation Trust, London, UK
Chinmay M Gupte, FRCS(Tr & Orth), PhD, MA (Oxon), MRCS
Specialist Registrar, St Mary's Hospital and North West Thames, London, UK

Carole M Hackney, BSc (Hons), PhD
Professor of Auditory Neuroscience, MacKay Institute of Communication and Neuroscience, School of Life Sciences, Keele University, Keele, UK

Peter A Helliewell, FIBMS, CSci, CBA, Cert Ed
Chief Scientist and Manager, Molecular and Cell Biology Unit, Department of Cellular Pathology, Royal Cornwall Hospital, Truro, UK

John M Hutson, AO
Professor of Paediatric Surgery, University of Melbourne, Department of Urology, Royal Children's Hospital, Parkville, Australia

Alan Jackson, BSc (Hons), PhD, MRCP, FRCR, FRCP
Professor of Radiology Imaging, Science and Biomedical Engineering, Wolfson Molecular Imaging Centre, The University of Manchester, Manchester, UK

Bruce W Jafek, MD, FACS, FRSM
Professor and Former Chairman (1976–1998), Department of Otolaryngology, Head and Neck Surgery, University of Colorado School of Medicine, Denver, Colorado, USA

Eric R Jauniaux, MD, PhD, MRCOG
Professor and Consultant in Materno-Fetal Medicine, Department of Obstetrics and Gynaecology, University College London Medical School, London, UK

Jonathan C Kentish, MA, PhD
Professor of Cellular Cardiology, Cardiovascular Division, King's College London, London, UK

Aadil A Khan, BM BCh, MPH, MRCS(Eng)
Speciality Trainee in Plastic Surgery, Oxford Region, UK

Khan Nasir, MBBS, MRCP, FRCR
Consultant Radiologist, Chelsea and Westminster Hospital
Royal Marsden Hospital, London, UK

W Niall A Kirkpatrick, BDS, MB BS, MD, FRCS, FRCS(Plast)
Consultant Craniofacial Plastic Surgeon, Craniofacial Unit, Chelsea and Westminster Hospital, London, UK

John G Lawrenson, BSc, PhD, MCOptom
Professor of Clinical Visual Science, Department of Optometry and Visual
Science, City University, London, UK

**Justin Lee, BSc, MBBS, MRCS(Eng), FRCR**
Consultant Radiologist, Department of Radiology, Chelsea and Westminster Hospital, London, UK

**David Lowe, MD, FRCS, FRCPath, FIBiol**
Consultant Histopathologist, The London Clinic, London, UK

HISTORICAL INTRODUCTION

The year 2008 sees the 150th anniversary of the publication of *Gray’s Anatomy*. The book is a rarity in textbook publishing in having been in continuous publication on both sides of the Atlantic Ocean, for so long. One and a half centuries is an exceptionally long era for a textbook, and of course the volume published now is very different from the one Mr. Henry Gray first created with his colleague Dr Henry Vandyke Carter, in mid-Victorian London. In this introductory essay, I shall explain the long history of Gray’s, from those Victorian days right up to today.

The shortcomings of existing anatomical textbooks probably impressed themselves upon Henry Gray when he was still a student at St George’s Hospital Medical School, near London's Hyde Park Corner, in the early 1840s. He began thinking about creating a new anatomy textbook a decade later, while war was being fought in the Crimea. New legislation was being planned which would establish the General Medical Council (1858) to regulate professional education and standards.

Gray was twenty-eight years old, and a teacher himself at St George’s. He was very able, hard-working, and highly ambitious, already a Fellow of the Royal Society, and of the Royal College of Surgeons. Although little is known about his personal life, his was a glittering career thus far, achieved while he served and taught on the hospital wards and in the dissecting room (Fig. 1).
Gray shared the idea for the new book with a talented colleague on the teaching staff at St George's, Henry Vandyke Carter, in November 1855. Carter was from a family of Scarborough artists, and was himself a clever artist and microscopist. He had produced fine illustrations for Gray's scientific publications before, but could see that this idea was a much more complex kind of a project. Carter recorded in his diary:

Little to record. Gray made proposal to assist by drawings in bringing out a Manual for students: a good idea but did not come to any plan … too exacting, for would not be a simple artist. (2)

Neither of these young men was interested in producing a pretty book, or an expensive one. Their purpose was to supply an affordable, accurate teaching aid for people like their own students, who might soon be required to operate on real patients, or on soldiers injured at Sebastopol or some other battlefield. The book they planned together was a practical one, designed to encourage youngsters to study anatomy, help them pass exams, and assist them as budding surgeons. It was not simply an anatomy textbook, but a guide to dissecting procedure, and to the major operations.

Gray and Carter belonged to a generation of anatomists ready to infuse the study of human anatomy with a new, and respectable, scientificity. Disreputable aspects of the profession's history, acquired during the days of bodysnatching, were assiduously being forgotten. The Anatomy Act of 1832 had legalized the requisition of unclaimed bodies from workhouse and hospital mortuaries, and the study of anatomy (now with its own Inspectorate) was rising in respectability in Britain. The private anatomy schools which had flourished in the Regency period were closing their doors, and the major teaching hospitals were erecting new purpose-built dissection rooms. (3)
The best-known student works when Gray and Carter had qualified were probably Erasmus Wilson's *Anatomist's Vade Mecum*, and *Elements of Anatomy* by Jones Quain. Both works were small – pocket-sized – but Quain came in two thick volumes. Both Quain's and Wilson's works were good books in their way, but their small pages of dense type, and even smaller illustrations, were somewhat daunting, seeming to demand much nose-to-the-grindstone effort from the reader.

The planned new textbook's dimensions and character were serious matters. Pocket manuals were commercially successful because they appealed to students by offering much knowledge in a small compass. But pocket-sized books had button-sized illustrations. Knox's *Manual of Human Anatomy*, for example, was a good book, but was only six inches by four (17 × 10 cm) and few of its illustrations occupied more than a third of a page. Gray and Carter must have discussed this matter between themselves, and with Gray's publisher JW Parker & Son, before decisions were taken about the size and girth of the new book, and especially the size of its illustrations.

The two men were earnestly engaged for the following eighteen months in the work which formed the basis of the book. All the dissections were undertaken jointly, Gray wrote the text, and Carter the illustrations. While Gray and Carter were working, a new edition of Quain's was published: this time it was a ‘triple-decker’ – in three volumes – of 1740 pages in all. Gray and Carter's working days were long, all the hours of daylight, eight or nine hours at a stretch – right through 1856, and well into 1857. We can infer from the warmth of Gray's appreciation of Carter in his published acknowledgements that their collaboration was a happy one.

The Author gratefully acknowledges the great services he has derived in the execution of this work, from the assistance of his friend, Dr. H. V. Carter, late Demonstrator of Anatomy at St George's Hospital. All the drawings from which the engravings were made, were executed by him. (4)

With all the dissections done, and Carter's inscribed wood-blocks at the engravers, Gray took six months' leave from his teaching at St George's to work as a personal doctor for a wealthy family. It was probably as good a way as any to get a well-earned break from the dissecting room and the dead-house. (5)

Carter sat the examination for medical officers in the East India Company, and sailed for India in the spring of 1858, when the book was still in its proof stages. Gray had left a trusted colleague, Timothy Holmes, to see the book through the press.

Gray looked over the final galley proofs, just before the book finally went to press. Timothy Holmes's association with the book's first edition would later prove vital to its survival.

**THE FIRST EDITION**

The book Gray and Carter had created together, *Anatomy, Descriptive and Surgical* appeared at the very end of August 1858, to immediate acclaim. Reviews in the *Lancet* and *British Medical Journal* were highly complimentary, and students flocked to buy.

It is not difficult to understand why it was a runaway success. Gray's *Anatomy* knocked its competitors into a cocked hat. The book holds well in the hand, it feels
substantial, and it contains everything required. It was considerably smaller and more slender than the doorstopper with which modern readers are familiar. To contemporaries it was small enough to be portable, but large enough for decent illustrations: ‘royal octavo’ – nine-and-a-half inches by six (24 × 15 cm) – about two-thirds of modern A4 size. Its medium size, single volume format was far removed from Quain, yet double the size of Knox’s Manual.

Simply organized and well designed, the book explains itself confidently and well: the clarity and authority of the prose is manifest. But what made it unique for its day was the outstanding size and quality of the illustrations. Gray thanked the wood engravers Butterworth and Heath for the ‘great care and fidelity’ they had displayed in the engravings, but it was really to Carter that the book owed its extraordinary success.

The beauty of Carter’s illustrations resides in their diagrammatic clarity, quite atypical for their time. The images in contemporary anatomy books were usually proxy labelled: dotted with tiny numbers or letters (often hard to find, or read) or bristling with a sheaf of numbered arrows, referring to a key situated elsewhere, usually in a footnote which was sometimes so lengthy it wrapped round onto the following page. Proxy labels require the reader’s eye to move to and fro: from the structure to the proxy label to the legend and back again. There was plenty of scope for slippage, annoyance and distraction. Carter’s illustrations, by contrast, unify name and structure, enabling the eye to assimilate both at a glance. We are so familiar with Carter’s images that it is hard to appreciate how incredibly modern they must have seemed in 1858. The volume made human anatomy look new, exciting, accessible, and do-able.

The first edition was covered in a light brown bookbinder’s cloth embossed all over in a dotted pattern, and a double picture-frame border. Its spine was lettered in gold blocking:
ANATOMICAL NOMENCLATURE

Anatomy is the study of the structure of the body. It is conventionally divided into topographical or gross anatomy (which includes surface, or 'living', anatomy, neuroanatomy, endoscopic and imaging anatomy), microscopic anatomy or histology and embryology (the study of the embryo and fetus).

Anatomical language is one of the fundamental languages of medicine. The unambiguous description of thousands of structures is impossible without an extensive and often highly specialized vocabulary. Ideally, these terms, which are often derived from Latin or Greek, should be used to the exclusion of any other, throughout the world. In reality, many terms are vernacularized. The Terminologia Anatomica, drawn up by the Federative Committee on Anatomical Terminology (FCAT) in 1998, has served as our guide in preparing the 39th and 40th Editions of Gray's Anatomy. Where we have anglicized some of the Latin terms, we have given the official form, at least once, in parentheses. We have also included eponyms, since these are often used, possibly more so by clinicians than anatomists. Indeed, certain eponyms are so firmly entrenched in the language of the clinician that to avoid them could lead to confusion: the eponymous term is often the only way to describe a particular structure, because there is no simple alternative anatomical term. (Short biographical details of the clinicians and anatomists whose names are used in this way are included in the electronic version of the book.)

PLANES, DIRECTIONS AND RELATIONSHIPS

To avoid ambiguity, all anatomical descriptions assume that the body is in the conventional 'anatomical position', i.e. standing erect and facing forwards, upper limbs by the side with the palms facing forwards, and lower limbs together with the toes facing forwards (Fig. 1). Descriptions are based on four imaginary planes, median, sagittal, coronal and horizontal, applied to a body in the anatomical position. The median plane passes longitudinally through the body and divides it into right and left halves. The sagittal plane is any vertical plane parallel with the median plane: although often used, 'parasagittal' is therefore redundant. The coronal (frontal) plane is orthogonal to the median plane and divides the body into anterior (front) and posterior (back). The horizontal (transverse) plane is orthogonal to both median and sagittal planes. Radiologists refer to transverse planes as (trans)axial: convention dictates that axial anatomy is viewed as though looking from the feet towards the head.
Fig. 1 The terminology widely used in descriptive anatomy. Abbreviations shown on arrows: AD, adduction; AB, abduction; FLEX, flexion (of the thigh at the hip joint); EXT, extension (of the leg at the knee joint).

Structures nearer the head are superior, cranial or (sometimes) cephalic, whereas structures closer to the feet are inferior; caudal is most often used in embryology to refer to the tail end of the embryo. Medial and lateral indicate closeness to the median plane, medial being closer than lateral: in the anatomical position, the little finger is medial to the thumb, the great toe is medial to the little toe. Specialized terms may also be used to indicate medial
and lateral. Thus, in the upper limb, ulnar and radial are used to mean medial and lateral respectively, and in the lower limb, tibial and fibular (peroneal) are used to mean medial and lateral respectively. Terms may be based on embryological relationships: the border of the upper limb that includes the thumb, and the border of the lower limb that includes the great toe are the pre-axial borders, whilst the opposite borders are the post-axial borders. Various degrees of obliquity are acknowledged using compound terms, e.g. posterolateral.

When referring to structures in the trunk and upper limb we have used freely the synonyms anterior, ventral, flexor, palmar, volar, and posterior, dorsal and extensor. We recognize that these synonyms are not always satisfactory, e.g. the extensor aspect of the leg is anterior with respect to the knee and ankle joints, and superior in the foot and digits; the plantar (flexor) aspect of the foot is inferior. Dorsal (dorsum) and ventral are terms used particularly by embryologists and neuroanatomists: they therefore feature most often in Sections 2 and 3.

Distal and proximal are used particularly to describe structures in the limbs, taking the datum point as the attachment of the limb to the trunk (sometimes referred to as the root), such that a proximal structure is closer to the attachment of the limb than a distal structure. However, proximal and distal are also used in describing branching structures, e.g. bronchi, vessels and nerves.

External (outer) and internal (inner) refer to the distance from the centre of an organ or cavity, e.g. the layers of the body wall, or the cortex and medulla of the kidney. Superficial and deep are used to describe the relationships between adjacent structures. Ipsilateral refers to the same side (of the body, organ or structure), bilateral to both sides, and contralateral to the opposite side.

Teeth are described using specific terms which indicate their relationship to their neighbours and to their position within the dental arch: these terms are described in Chapter 30.
BIBLIOGRAPHY OF SELECTED TITLES

The following references contain information relevant to numerous chapters in this edition. They are therefore cited here rather than at the end of individual chapters. For an extended historical bibliography, all references from the 38th edition are available on the website which accompanies Gray’s Anatomy.

TERMINOLOGY

The shapes of mammalian cells vary widely depending on their interactions with each other, their extracellular environment and internal structures. Their surfaces are often highly folded when absorptive or transport functions take place across their boundaries. Cell size is limited by rates of diffusion, either that of material entering or leaving cells, or of diffusion within them. Movement of macromolecules can be much accelerated and also directed by processes of active transport across membranes and by transport mechanisms within the cell. According to the location of absorptive or transport functions, apical microvilli (Fig. 1.1) or basolateral infoldings create a large surface area for transport or diffusion.

Motility is a characteristic of most cells, in the form of movements of cytoplasm or specific organelles from one part of the cell to another. It also includes: the extension of parts of the cell surface such as pseudopodia, lamellipodia, filopodia and microvilli; locomotion of entire cells as in the amoeboid migration of tissue macrophages; the beating of flagella or cilia to move the cell (e.g. in spermatozoa) or fluids overlying it.
(e.g. in respiratory epithelium); cell division and muscle contraction. Cell movements are also involved in the uptake of materials from their environment (endocytosis, phagocytosis) and the passage of large molecular complexes out of cells (exocytosis, secretion).

Cells rarely operate independently of each other and commonly form aggregates by adhesion, often assisted by specialized intercellular junctions. They may also communicate with each other either by generating and detecting molecular signals that diffuse across intercellular spaces, or more rapidly by membrane contact, which may involve small, transient, transmembrane channels or interactions between membrane-bound signalling molecules. Cohesive groups of cells constitute tissues and more complex assemblies of tissues form functional systems or organs.

Most cells are between 5–50 μm in diameter: e.g. resting lymphocytes are 6 μm across, red blood cells 7.5 μm and columnar epithelial cells are 20 μm tall and 10 μm wide (all measurements are approximate). Some cells are much larger than this: e.g. megakaryocytes of the bone marrow are more than 200 μm in diameter. Large neurones and skeletal muscle cells have relatively enormous volumes because of their extended shapes, some of the former being over 1 metre in length.
CELLULAR ORGANIZATION

Each cell is contained within its limiting plasma, or surface, membrane which encloses the cytoplasm. All cells except mature red blood cells also contain a nucleus that is surrounded by a nuclear membrane or envelope (Fig. 1.1, Fig. 1.2). The nucleus includes the genome of the cell contained within the chromosomes, the nucleolus, and other sub-nuclear organelles. The cytoplasm contains several systems of organelles. These include a series of membrane-bound structures that form separate compartments within the cytoplasm, such as rough and smooth endoplasmic reticulum, Golgi apparatus, lysosomes, peroxisomes, mitochondria and vesicles for transport, secretion and storage of cellular components. There are also structures that lie free in the non-membranous, cytosolic compartment. They include ribosomes and several filamentous protein networks known collectively as the cytoskeleton. The cytoskeleton determines general cell shape and supports specialized extensions of the cell surface (microvilli, cilia, flagella). It is involved in the assembly of new filamentous organelles (e.g. centrioles) and controls internal movements of the cytoplasm and cytoplasmic vesicles. The cytosol contains many soluble proteins, ions and metabolites.
**Fig. 1.2** The structural organization and some principal organelles of a typical cell. This example is a ciliated columnar epithelial cell from human nasal mucosa. The central cell, which occupies most of the field of view, is closely apposed to its neighbours along their lateral plasma membranes. Within the apical junctional complex, these membranes form a tightly sealed zone (tight junction) that isolates underlying tissues from, in this instance, the nasal cavity. AJC, apical junctional complex; APM, apical plasma membrane; C, cilia; Cy, cytoplasm; EN, euchromatic nucleus; LPM, lateral plasma membrane; M, mitochondria; MV, microvilli; N, nucleolus.

**Cell polarity and domains**

Epithelia (including endothelia and mesothelia) are organized into sheets or more complex structures (see Ch. 2) with very different environments on either side. These cells actively transfer macromolecules and ions between the two surfaces and are thus polarized in structure and function (Fig. 1.3). In polarized cells, particularly in epithelia, the cell is generally subdivided into domains that reflect the polarization of activities within it. The free surface, e.g. that facing the intestinal lumen or airway, is the apical surface, and its adjacent cytoplasm is the apical cell domain. This is where
the cell interfaces with a specific body compartment (or, in the case of the epidermis, with the outside world). The apical surface is specialized to act as a barrier, restricting access of substances from this compartment to the rest of the body. Specific components are selectively absorbed from, or added to, the external compartment by the active processes, respectively, of active transport and endocytosis inwardly or exocytosis and secretion outwardly. The apical surface is often covered with small protrusions of the cell surface, microvilli, which increase the surface area, particularly for absorption.

Fig. 1.3 Absorptive epithelium from human colon, immunolabelled to show the functional division of cell surface domains. CD66 antigen expression (red) is concentrated in the apical domain facing the gut lumen (top), on striated border microvilli; diffuse labelling is present throughout the cytoplasm but is excluded from the basal zone occupied by nuclei. The intestinal cell antigen A33 (green) is a member of the immunoglobulin superfamily of transmembrane proteins, expressed here on basolateral cell surfaces.

(By courtesy of Cécile Chalouni, Ludwig Institute for Cancer Research, Yale University School of Medicine.)

The surface of the cell opposite to the apical surface is the basal surface, with its associated basal cell domain. In a single-layered epithelium, this surface is apposed to the basal lamina. The remaining surfaces are known as the lateral cell surfaces. In many instances the lateral and basal surfaces perform similar functions and the cellular domain is termed the basolateral domain. Cells actively transport substances, such as digested nutrients from the intestinal lumen or endocrine secretions, across their basal (or basolateral) surfaces into the subjacent connective tissue matrix and
the blood capillaries within it. Dissolved non-polar gases (oxygen and carbon dioxide) diffuse freely between the cell and the bloodstream across the basolateral surface. Apical and basolateral surfaces are separated by a tight intercellular seal, the tight junction, which prevents the passage of even small ions through the space between adjacent cells and thus maintains the difference between environments either side of the epithelium.
PLASMA MEMBRANE

Cells are bounded by a distinct plasma membrane, which shares features with the system of internal membranes that compartmentalize the cytoplasm and surround the nucleus. They are all composed of lipids (mainly phospholipids, cholesterol and glycolipids) and proteins, in approximately equal ratios. Plasma membrane lipids form a layer two molecules thick, the lipid bilayer. The hydrophobic ends of each lipid molecule face the interior of the membrane and the hydrophilic ends face outwards. Most proteins are embedded within, or float in, the lipid bilayer as a fluid mosaic. Some proteins, because of extensive hydrophobic regions of their polypeptide chains, span the entire width of the membrane (transmembrane proteins), whereas others are only superficially attached to the bilayer by lipid groups. Both are integral (intrinsic) membrane proteins, as distinct from peripheral (extrinsic) membrane proteins, which are membrane-bound only through their association with other proteins. Carbohydrates in the form of oligosaccharides and polysaccharides are bound either to proteins (glycoproteins) or to lipids (glycolipids), and project mainly into the extracellular domain.

Combinations of biochemical, biophysical and biological techniques have revealed that lipids are not homogeneously distributed in membranes, but that some are organized into microdomains in the bilayer, called ‘detergent-resistant membranes’ or lipid ‘rafts’, rich in sphingomyelin and cholesterol (Morris et al 2004). The ability of select subsets of proteins to partition into different lipid microdomains has profound effects on their function, e.g. in T-cell receptor and neurotrophin signalling. The highly organized environment of the domains provides a signalling, trafficking and membrane fusion environment very different from that found in the disorganized fluid mosaic membrane.

In the electron microscope, membranes fixed and contrasted by heavy metals such as osmium appear in section as two densely stained layers separated by an electron-translucent zone – the classic unit membrane (Fig. 1.4). The total thickness is about 5 nm. Freeze-fracture cleavage planes usually pass along the midline of each membrane, where the hydrophobic tails of phospholipids meet. This technique has also demonstrated intramembranous particles embedded in the lipid bilayer; these are in the 5–15 nm range and in most cases represent large transmembrane protein molecules or complexes of molecules. Intramembranous particles are distributed asymmetrically between the two half-membranes, usually adhering more to one face than to the other. In plasma membranes, the inner or protoplasmic (cytoplasmic) half-membrane carries most particles, seen on its surface facing the exterior (the P face). Where they have been identified, particles usually represent channels for the transmembrane passage of ions or molecules.
Fig. 1.4 The molecular organization of the plasma membrane, according to the fluid mosaic model of membrane structure. Intrinsic or integral membrane proteins include diffusion or transport channel complexes, receptor proteins and adhesion molecules. These may span the thickness of the membrane (transmembrane proteins) and can have both extracellular and cytoplasmic domains. Transmembrane proteins have hydrophobic zones, which cross the phospholipid bilayer and allow the protein to ‘float’ in the plane of the membrane. Some proteins are restricted in their freedom of movement where their cytoplasmic domains are tethered to the cytoskeleton.

Biophysical measurements show the lipid bilayer to be highly fluid, allowing diffusion in the plane of the membrane. Thus proteins are able to move freely in such planes unless anchored from within the cell. Membranes in general, and the plasma membrane in particular, form boundaries selectively limiting diffusion and creating physiologically distinct compartments. Lipid bilayers are impermeable to hydrophilic solutes and ions and so membranes actively control the passage of ions and small organic molecules such as nutrients, through the activity of membrane transport proteins. However, lipid-soluble substances can pass directly through the membrane so that, for example, steroid hormones enter the cytoplasm freely. Their receptor
proteins are either cytosolic or nuclear, rather than being located on the cell surface.

Plasma membranes are able to generate electrochemical gradients and potential differences by selective ion transport, and actively take up or export small molecules by energy dependent processes. They also provide surfaces for the attachment of enzymes, sites for the receptors of external signals, including hormones and other ligands, and sites for the recognition and attachment of other cells. Internally, plasma membranes can act as points of attachment for intracellular structures, in particular those concerned with motility and other cytoskeletal functions. Cell membranes are synthesized by the rough endoplasmic reticulum in conjunction with the Golgi apparatus.

**The cell coat (glycocalyx)**

The plasma membrane differs structurally from internal membranes in that it possesses an external, diffuse, carbohydrate-rich coat, the cell coat or glycocalyx. The cell coat forms an integral part of the plasma membrane, projecting as a diffusely filamentous layer 2–20 nm or more from the lipoprotein surface (see Fig. 1.5). The overall thickness of the plasma membrane is therefore variable, but is typically 8–10 nm. The cell coat is composed of the carbohydrate portions of glycoproteins and glycolipids embedded in the plasma membrane (Fig. 1.4).
The precise composition of the glycocalyx varies with cell type: many tissue and cell type-specific antigens are located in the coat, including the major histocompatibility antigen systems and, in the case of erythrocytes, blood group antigens. It also contains adhesion molecules, which enable cells to adhere selectively to other cells or to the extracellular matrix. They have important roles in maintaining the integrity of tissues and in a wide range of dynamic cellular processes, e.g. the formation of intercommunicating neural networks in the developing nervous system and the extravasation of leukocytes. Cells tend to repel each other because of the predominance of negatively charged carbohydrates at cell surfaces. There is consequently a distance of at least 20 nm between the plasma membranes of adjacent cells, other than at specialized junctions.

**Cell surface contacts**

The plasma membrane is the surface which establishes contact with other cells and with structural components of extracellular matrices. These contacts may have a predominantly adhesive role, or initiate instructive signals within and between cells, or both; they frequently affect the behaviour of cells. Structurally, there are two main classes of contact, both associated with cell adhesion molecules. One class is associated with specializations at discrete regions of the cell surface that are ultrastructurally distinct. These are described on page 6. The second, general, class of
adhesive contact has no obvious associated ultrastructural features.

**General adhesive contacts**

One class of transmembrane or membrane-anchored glycoproteins that project externally from the plasma membrane, and which form adhesive contacts, are the cell adhesion molecules. There are a number of molecular subgroups, which are broadly divisible on the basis of their calcium dependence. Their numerous functions include tissue formation and morphogenesis and there is evidence for coordinated interaction between the subgroups.

**Calcium-dependent adhesion molecules**

Cadherins, selectins and integrins are calcium-dependent adhesion molecules. Cadherins are transmembrane proteins, with five heavily glycosylated external domains. They are responsible for strong general intercellular adhesion, as well as being components of some specialized adhesive contacts, and are attached by linker proteins (catenins) at their cytoplasmic ends to underlying cytoskeletal fibres (either actin or intermediate filaments). Different cell types possess different members of the cadherin family, e.g. N-cadherins in nervous tissue, E-cadherins in epithelia, and P-cadherins in the placenta. These molecules bind to those of the same type in other cells (homophilic binding), so that cells of the same class adhere to each other preferentially, forming tissue aggregates or layers, as in epithelia. For a review of cadherin-mediated adhesion in morphogenesis, see Gumbiner (2005).

Selectins are found on leukocytes, platelets and vascular endothelial cells. They are transmembrane lectin glycoproteins that can bind with low affinity to the carbohydrate groups on other cell surfaces to permit movement between the two, e.g. the rolling adhesion of leukocytes on the walls of blood vessels (p. 136). They function cooperatively in sequence with integrins, which strengthen the selectin adhesion.

Integrins are glycoproteins that typically mediate adhesion between cells and extracellular matrix components such as fibronectin, collagen, laminin. They integrate interactions between the matrix and the cell cytoskeleton to which they are linked, and so facilitate cell migration within the matrix. An integrin molecule is formed of two subunits (α and β), each of which has several subtypes. Combinations of alternative subunits provide some 24 known integrin heterodimers, each one directed to a particular extracellular molecule, although there is considerable overlap in specificity. Some integrins depend for their binding on magnesium, rather than calcium.

**Calcium-independent adhesion molecules**

The best known calcium-independent adhesion molecules are glycoproteins that have external domains related to immunoglobulin molecules. Most are transmembrane proteins. Some are entirely external, either attached to the plasma membrane by a glycosylphosphatidylinositol anchor, or secreted as soluble components of the extracellular matrix. Different types are expressed in different tissues. Neural cell adhesion molecules (N-CAMs) are found on a number of cell types, but are expressed widely by neural cells. Intercellular adhesion molecules (I-CAMs) are expressed on vascular endothelial cells. Cell adhesion molecule binding is predominantly homophilic, although some use a heterophilic mechanism, e.g. vascular intercellular adhesion molecule (VCAM), which can bind to integrins.
For further information on all aspects of cell adhesion molecules and intercellular contacts, see Pollard & Earnshaw (2007).

**Specialized adhesive contacts**

Specialized adhesive contacts, some of which mediate activities other than simple mechanical cohesion, are localized regions of the cell surface with particular ultrastructural characteristics. Three major classes exist: occluding, adhesive and communicating junctions (Fig. 1.5).

**Occluding junctions (tight junctions, zonula occludens)**

Occluding junctions create diffusion barriers in continuous layers of cells, including epithelia, mesothelia and endothelia, and prevent the passage of materials across the cellular layer through intercellular spaces. They form a continuous belt (zonula) around the cell perimeter, near the apical surface in cuboidal or columnar epithelial cells. At a tight junction, the membranes of the adjacent cells come into contact, so that the gap between them is obliterated. Freeze-fracture electron microscopy shows that the contacts between the membranes lie along branching and anastomosing ridges formed by the incorporation of chains of intramembranous protein particles on the P face of the lipid bilayer (Fig. 1.5C).

This arrangement ensures that substances can only pass through the layer of cells by diffusion or transport through their apical membranes and cytoplasm. The cells thus selectively modify the environment on either side of the layer. Occluding junctions also create regional differences in the plasma membranes of the cells in which they are found. For example, in epithelia, the composition of the apical plasma membrane differs from that of the basolateral regions (see Fig. 1.3), and this allows these regions to engage in functions such as directional transport of ions and uptake of macromolecules. Because tight junctions have high concentrations of fixed transmembrane proteins, they act as barriers to lateral diffusion of lipid and protein within membranes. The integrity of tight junctions is calcium-dependent. Cells can transiently alter the permeability of their tight junctions to increase passive paracellular transport in some circumstances.

**Adhesive junctions**

Adhesive junctions include intercellular and cell–extracellular matrix contacts, where cells adhere strongly to each other or to adjacent matrix components. Intercellular contacts can be subdivided according to the extent and location of the contact. They all display a high concentration of cell adhesion molecules, which externally bind adjacent cells, and internally link to the cytoskeleton via intermediary proteins.

**Zonula adherens (intermediate junction)**

A zonula adherens is a continuous, belt-like zone of adhesion around the apical perimeters of epithelial, mesothelial and endothelial cells, parallel and just basal to the tight junction in epithelia. High concentrations of cadherins occur in this zone; their cytoplasmic ends are anchored via the proteins vinculin and α-actinin to a layer of actin microfilaments. These junctions help to reinforce the intercellular attachment of the tight junction and prevent its mechanical disruption. The gap between cell surfaces is about 20 nm. Usually, no electron-dense material is observed within this
intercellular space.

**Fascia adherens**

A fascia adherens is similar to a zonula adherens, but is more limited in extent and forms a strip or patch of adhesion, e.g. between smooth muscle cells, in the intercalated discs of cardiac muscle cells and between glial cells and neurones. The junctions involve cadherins attached indirectly to actin filaments on the inner side of the membrane.

**Desmosomes (maculae adherentes)**

Desmosomes are limited, plaque-like areas of particularly strong intercellular contact. They can be located anywhere on the cell surface. In epithelial cells, there may be a circumferential row of desmosomes parallel to the tight and intermediate junctional zones, an arrangement that forms the third, most basally situated, component of the epithelial apical junctional complex (Fig. 1.5). The intercellular gap is approximately 25 nm, is filled with electron-dense filamentous material running transversely across it and is also marked by a series of densely staining bands running parallel to the cell surfaces. Adhesion is mediated by calcium-dependent cadherins, desmoglein and desmocollin. Within the cells on either side, a cytoplasmic density underlies the plasma membrane and includes the anchor proteins desmoplakin and plakoglobin, into which the ends of intermediate filaments are inserted. The type of intermediate filament depends on cell type, e.g. keratins are found in epithelia and desmin filaments in cardiac muscle cells. Desmosomes form strong anchorage points, likened to spot-welds, between cells subject to mechanical stress, e.g. in the prickle cell layer of the epidermis, where they are extremely numerous and large.

**Hemidesmosomes**

Hemidesmosomes are best known as anchoring junctions between the bases of epithelial cells and the basal lamina. Ultrastructurally, they resemble a single-sided desmosome, anchored on one side to the plasma membrane, and on the other to the basal lamina and adjacent collagen fibrils (Fig. 1.5D and see Fig. 7.5). On the cytoplasmic side of the membrane there is a dense plaque into which keratin filaments are inserted. Hemidesmosomes use integrins as their adhesion molecules, whereas desmosomes use cadherins.

Less highly structured attachments with a similar arrangement exist between many other cell types and their surrounding matrix, e.g. between smooth muscle cells and their matrix fibrils, and between the ends of skeletal muscle cells and tendon fibres. The smaller, punctate adhesions resemble focal adhesion plaques.

**Focal adhesion plaques**

Focal adhesion plaques are regions of local attachment between cells and the extracellular matrix. They are typically situated at or near the ends of actin filament bundles (stress fibres), which are anchored through intermediary proteins to the cytoplasmic domains of integrins. In turn, these are attached at their external ends to collagen or other filamentous structures in the extracellular matrix. They are usually short-lived: their formation and subsequent disruption are part of the motile behaviour of migratory cells.
Gap junctions (communicating junctions)

Gap junctions resemble tight junctions in transverse section, but the two apposed lipid bilayers are separated by an apparent gap of 3 nm which is bridged by numerous transmembrane channels (connexons). Connexons are formed by a ring of six connexin proteins in each membrane. Their external surfaces meet those of the adjacent cell in the middle. A minute central pore links one cell to the next (Fig. 1.5). These channels may exist in small numbers, and this makes them difficult to detect structurally. However, they lower the transcellular electrical resistance and so can be detected by microelectrodes. Larger assemblies of many thousands of channels are often packed in hexagonal arrays (Fig. 1.5B). Such junctions form limited attachment plaques rather than continuous zones, and so allow free passage of substances within the adjacent intercellular space, unlike tight junctions. They occur in numerous tissues including the liver, epidermis, pancreatic islet cells, connective tissues, cardiac muscle and smooth muscle, and are also common in embryonic tissues. In the central nervous system, they are found in the ependyma and between neuroglial cells, and they form electrical synapses between some types of neurone, although this is rare in humans. Very recently, a second family of gap junctional proteins has been discovered, the pannexins. In humans, expression of pannexins has been most extensively studied in the nervous system (reviewed in Litvin et al 2006).

Although gap junctions form diffusion channels between cells, the size of their apertures limits diffusion to small molecules and ions (up to a molecular weight of about 1000 kDa). Thus they admit sodium, potassium and calcium ions, various second messenger components, and a number of metabolites, but they exclude messenger RNA and other macromolecules. In some excitable tissues (e.g. cardiac and smooth muscle), one cell can activate another electrically by current flow through gap junctions. Communicating junctions probably permit metabolic cooperation between groups of adjacent cells; the significance of this activity in embryogenesis, normal tissue function, homeostasis and repair is only beginning to be understood.

Other types of junction

Chemical synapses and neuromuscular junctions are specialized areas of intercellular adhesion where neurotransmitters secreted from a neuronal terminal gain access to specialized receptor molecules on a recipient cell surface. They are described on pages 44 and 62, respectively.

Cell signalling

Cellular systems in the body communicate with each other to coordinate and integrate their functions. This occurs through a variety of processes known collectively as cell signalling, in which a signalling molecule produced by one cell is detected by another, almost always by means of a specific receptor protein molecule. The recipient cell transduces the signal, which it most usually detects at the plasma membrane, into intracellular chemical messages that change cell behaviour.

The signal may act over a long distance, e.g. endocrine signalling through the release of hormones into the bloodstream, or neuronal synaptic signalling via electrical impulse transmission along axons and subsequent release of chemical transmitters of the signal at synapses (p. 44) or neuromuscular junctions (p. 62). A specialized variation of endocrine signalling (neurocrine or neuroendocrine signalling) occurs
when neurones or paraneurones (e.g. chromaffin cells of the suprarenal medulla) secrete a hormone into interstitial fluid and the bloodstream.

Alternatively, signalling may occur at short range through a paracrine mechanism, in which cells of one type release molecules into the interstitial fluid of the local environment, to be detected by nearby cells of a different type that express the specific receptor protein. Neurocrine cell signalling uses chemical messengers found also in the central nervous system which may act in a paracrine manner via interstitial fluid or reach more distant target tissues in the bloodstream. Cells may generate and respond to the same signal. This is autocrine signalling, a phenomenon that reinforces the coordinated activities of a group of like cells, which respond together to a high concentration of a local signalling molecule. The most extreme form of short-distance signalling is contact-dependent (juxtacrine) signalling, where one cell responds to transmembrane proteins of an adjacent cell that bind to surface receptors in the responding cell membrane. Contact-dependent signalling also includes cellular responses to integrins on its surface binding to elements of the extracellular matrix. Juxtacrine signalling is important during development and in immune responses.

These different types of intercellular signalling mechanism are illustrated in Figure 1.6. For further reading, see Alberts et al (2002) and Pollard & Earnshaw (2007).
Signalling molecules and their receptors

The majority of signalling molecules (ligands) are hydrophilic. They cannot cross the plasma membrane of a recipient cell to effect changes intracellularly unless they first bind to a plasma membrane receptor protein. Ligands are mainly proteins (usually glycoproteins), polypeptides or highly charged biogenic amines. They include: classic peptide hormones of the endocrine system; cytokines, which are mainly of haemopoietic cell origin and involved in inflammatory responses and tissue remodelling (e.g. the interferons, interleukins, tumour necrosis factor, leukaemia inhibitory factor); polypeptide growth factors (e.g. the epidermal growth factor superfamily, nerve growth factor, platelet-derived growth factor, the fibroblast growth factor family, transforming growth factor beta and the insulin-like growth factors). Polypeptide growth factors are multifunctional molecules with more widespread actions and cellular sources than their names suggest. They and their receptors are commonly mutated or aberrantly expressed in certain cancers. The cancer-causing gene variant is termed a transforming oncogene and the normal (wild-type) version of the gene is a cellular oncogene or proto-oncogene. The activated receptor acts as a transducer to generate intracellular signals, which are either small diffusible second messengers (e.g. calcium, cyclic adenosine monophosphate or the plasma membrane lipid-soluble diacylglycerol), or larger protein complexes that amplify and relay the signal to target control systems. For further reading on growth factors and other signalling molecules, see Epstein (2003).

Some signals are hydrophobic and able to cross the plasma membrane freely. Classic examples are the steroid hormones, thyroid hormones, retinoids and vitamin D. Steroids, for instance, enter cells non-selectively, but elicit a specific response only in those target cells which express specific cytoplasmic or nuclear receptors. Light stimuli also cross the plasma membranes of photoreceptor cells and interact intracellularly, at least in rod cells, with membrane-bound photosensitive receptor proteins. Hydrophobic ligands are transported in the bloodstream or interstitial fluids, generally bound to carrier proteins, and they often have a longer half-life and longer-lasting effects on their targets than do water-soluble ligands.

A separate group of signalling molecules that are able to cross the plasma membrane freely is typified by the gas, nitric oxide. The principal target of short-range nitric oxide signalling is smooth muscle, which relaxes in response. Nitric oxide is released from vascular endothelium as a result of the action of autonomic nerves that supply the vessel wall. It causes local relaxation of smooth muscle and dilation of vessels. In the penis, this mechanism is responsible for penile erection. Nitric oxide is unusual among signalling molecules in having no specific receptor protein; instead, it acts directly on intracellular enzymes of the response pathway.

Receptor proteins

There are some 20 different families of receptor proteins, each with several isoforms responding to different ligands. The great majority of these receptors are transmembrane proteins. Members of each family share structural features that
indicate either shared ligand-binding characteristics in the extracellular domain or shared signal transduction properties in the cytoplasmic domain, or both. There is little relationship either between the nature of a ligand and the family of receptor proteins to which it binds and activates, or the signal transduction strategies by which an intracellular response is achieved. The same ligand may activate fundamentally different types of receptor in different cell types.

Cell surface receptor proteins are generally grouped according to their linkage to one of three intracellular systems: ion channel-linked receptors; G-protein-coupled receptors; receptors that link to enzyme systems. Other receptors do not fit neatly into any of these categories. All the known G-protein-coupled receptors belong to a structural group of proteins that pass through the membrane seven times in a series of serpentine loops. These receptors are thus known as seven-pass transmembrane receptors or, because the transmembrane regions are formed from α-helical domains, as seven-helix receptors. The most well-known of this large group of phylogenetically ancient receptors are the odorant-binding proteins of the olfactory system, the light-sensitive receptor protein, rhodopsin, and many of the receptors for clinically useful drugs. A comprehensive list of receptor proteins, their activating ligands and examples of the resultant biological function, is given in Pollard & Earnshaw (2007).

**Intracellular signalling**

A wide variety of small molecules carry signals within cells, conveying the signal from its source (e.g. activated plasma membrane receptor) to its target (e.g. the nucleus). These second messengers convey signals as fluctuations in local concentration, according to rates of synthesis and degradation by specific enzymes (e.g. cyclases involved in cyclic nucleotide (cAMP, cGMP) synthesis), or, in the case of calcium, according to the activities of calcium channels and pumps. Other, lipidic, second messengers such as phosphatidylinositol, derive from membranes and may act within the membrane to generate downstream effects. For further consideration of the complexity of intracellular signalling pathways, see Pollard & Earnshaw (2007).

**Transport across cell membranes**

Lipid bilayers are increasingly impermeable to molecules as they increase in size or hydrophilicity. Transport mechanisms are therefore required to carry essential polar molecules, including ions, nutrients, nucleotides and metabolites of various kinds, across the plasma membrane and into or out of membrane-bound intracellular compartments. Transport is facilitated by a variety of membrane transport proteins, each with specificity for a particular class of molecule, e.g. sugars. Transport proteins fall mainly into two major classes, channel proteins and carrier proteins.

Channel proteins form aqueous pores in the membrane, which open and close under the regulation of intracellular signals, e.g. G-proteins, to allow the flux of solutes (usually inorganic ions) of specific size and charge. Transport through ion channels is always passive and ion flow through an open channel depends only on the ion concentration gradient and its electronic charge, and the potential difference across the membrane. These factors combine to produce an electrochemical gradient, which governs ion flux. Channel proteins are utilized most effectively by the excitable plasma membranes of nerve cells, where the resting membrane potential can change transiently from about −80 mV (negative inside the cell) to +40 mV (positive inside the
cell) when stimulated by a neurotransmitter (as a result of the opening and subsequent closure of channels selectively permeable to sodium and potassium).

Carrier proteins bind their specific solutes, such as amino-acids, and transport them across the membrane through a series of conformational changes. This latter process is slower than ion transport through membrane channels. Transport by carrier proteins can occur either passively by simple diffusion, or actively against the electrochemical gradient of the solute. Active transport must therefore be coupled to a source of energy, such as ATP generation, or energy released by the coordinate movement of an ion down its electrochemical gradient. Linked transport can be in the same direction as the solute, in which case the carrier protein is described as a symporter, or in the opposite direction, when the carrier acts as an antiporter.

Translocation of proteins across intracellular membranes

Proteins are generally synthesized on ribosomes in the cytosol or on the rough endoplasmic reticulum. A few are made on mitochondrial ribosomes. Once synthesized, many proteins remain in the cytosol, where they carry out their functions. Others, such as integral membrane proteins or proteins for secretion, are translocated across intracellular membranes for post-translational modification and targeting to their destinations. This is achieved by the signal sequence, an addressing system contained within the protein sequence of amino-acids, which is recognized by receptors or translocators in the appropriate membrane. Proteins are thus sorted by their signal sequence (or set of sequences that become spatially grouped as a signal patch when the protein folds into its tertiary configuration), so that they are recognized by and enter the correct intracellular membrane compartment.

Exocytosis and endocytosis

Secreted proteins, lipids, mucins, small molecules such as amines and other cellular products destined for export from the cell are transported to the plasma membrane in small vesicles released from the trans face of the Golgi apparatus. This pathway is either constitutive, in which transport and secretion occur more or less continuously, or it is regulated by external signals, as in the control of salivary secretion by autonomic neural stimulation. In regulated secretion, the secretory product is stored temporarily in membrane-bound secretory granules or vesicles. Exocytosis is achieved by fusion of the secretory vesicular membrane with the plasma membrane and release of the vesicle contents into the extracellular domain.

In polarized cells, e.g. most epithelia, exocytosis occurs at the apical plasma membrane and the cells secrete into a duct lumen or onto a free surface such as the lining of the stomach. In hepatocytes, bile is secreted across a very small area of plasma membrane forming the wall of the bile canaliculus. This region is defined as the apical plasma membrane, and is the site of exocrine secretion, whereas secretion of hepatocyte plasma proteins into the bloodstream is targeted to the basolateral surfaces facing the sinusoids. Packaging of different secretory products into appropriate vesicles takes place in the trans-Golgi network. Delivery of secretory vesicles to their correct plasma membrane domains is achieved by sorting sequences in the cytoplasmic tails of vesicular membrane proteins.

There are other mechanisms in which initial delivery of secretory products is less
selective, but is followed by selective retention (or degradation) or reprocessing and redistribution by endosomes. Ultimately, secretory vesicles undergo docking, priming (to prepare the vesicle for a regulatory signal, where secretion is regulation-dependent) and fusion with the plasma membrane to release their contents. The process of exocytosis also delivers integral membrane components to the cell surface in the normal turnover and recycling of the plasma membrane. However, excess plasma membrane generated by vesicle fusion during exocytosis is rapidly removed by concurrent endocytosis.

The process of endocytosis involves the internalization of vesicles derived from the plasma membrane. The vesicles may contain: engulfed fluids and solutes from the extracellular interstitial fluid (pinocytosis); larger macromolecules, often bound to surface receptors (receptor-mediated endocytosis); particulate matter, including microorganisms or cellular debris (phagocytosis). Pinocytosis generally involves small fluid-filled vesicles and is a marked property of capillary endothelium, e.g. where vesicles containing nutrients and oxygen dissolved in blood plasma are transported from the vascular lumen to the endothelial basal plasma membrane (see Fig. 6.11). Interstitial fluid containing dissolved carbon dioxide is also taken up by pinocytosis for simultaneous transportation across the endothelial cell wall in the opposite direction, for release into the bloodstream by exocytosis. This shuttling of pinocytotic vesicles is also termed transcytosis. Larger volumes of fluid are engulfed by dendritic cells, e.g. in the process of sampling interstitial fluids by macropinocytosis in immune surveillance for antigens (p. 79). Interstitial fluid is inevitably taken up during receptor-mediated endocytosis when ligands are internalized.

Receptor-mediated endocytosis, also known as clathrin-dependent endocytosis, is initiated at specialized regions of the plasma membrane known as clathrin-coated pits. Clathrin is a protein that cross-links adjacent adaptor protein (adaptin) complexes to form a basket-like structure, bending the membrane inwards into a hemisphere. Much, but not all, fluid-phase pinocytosis also utilizes clathrin-coated pits. Ligands such as the iron-transporting protein, transferrin, and the cholesterol-transporting low-density lipoprotein bind to their receptors, which cluster in clathrin-coated pits through an interaction with adaptins. The pits then invaginate and pinch off from the plasma membrane, internalizing both receptor and ligand. The processing of endocytic vesicles and their contents is described on p. 12. For further details of the molecular mechanisms of endocytosis, see Alberts et al (2002) or Pollard & Earnshaw (2007).

**Phagocytosis**

Phagocytosis is a property of many cell types, but is most efficient in cells specialized for this activity. The professional phagocytes of the body belong to the monocyte lineage of haemopoietic cells, in particular the tissue macrophages (p. 78). Other effective phagocytes are neutrophil granulocytes and most dendritic cells (p. 79), which are also of haemopoietic origin. Phagocytosis plays an important part in the immune defence system of the body, in which the amoeboid process of ingestion of organisms for nutrition has evolved into a mechanism for the clearance of microorganisms invading the body. Macrophages also ingest particulate material including inorganic matter, such as inhaled dust particles, in addition to debris from dead cells and protein aggregates such as immune complexes in the blood, airways, interstitial spaces and connective tissue matrices.
Phagocytosis is a triggered process, initiated when a phagocytic cell binds to a particle or organism, often through a process of molecular recognition. Typically, a pathogenic microorganism may first be coated by antibodies, which are bound in turn by receptors for the Fc portion of the antibody molecule expressed by macrophages and neutrophils; in this way the microorganism is attached to the cell. This triggers the production of large pseudopodia, which engulf the organism and internalize it, as their pseudopod tips fuse together. The process appears to depend on actin–myosin-based cellular motility and, unlike receptor-mediated endocytosis, it is energy dependent. Phagosomes thus formed are as large as the body they engulf and can be a considerable proportion of the volume of the phagocytic cell. Inside the cell, the phagosome fuses with lysosomes, which degrade its contents.
CYTOPLASM

Compartment and functional organization

The cytoplasm is highly concentrated, with about 200 mg/ml of proteins (about twice the concentration in blood) that must be precisely organized for correct molecular interactions to occur. It normally has extremely low levels of Ca\(^{2+}\), high K\(^{+}\) and low Na\(^{+}\) ions in comparison to extracellular fluid, differences which are important in cell signalling. Cytoplasm is also reductive, a state maintained by a high concentration of thiol-containing glutathione. The cell is able to undertake completely opposite reactions simultaneously (e.g. the synthesis and degradation of proteins; growth at one end of a cell with retraction at another) by partitioning them into different regions of the cytoplasm. The most fundamental divide is the use of oxidative reactions within the reductive cytoplasm, achieved by the compartmentalization of different environments within membranes. For example, the endoplasmic reticulum is comprised of stacks of tubules, whose lumen resembles the extracellular environment in being oxidative and Ca\(^{2+}\)-rich, predominantly encrusted on the external (cytoplasmic) face with attached ribosomes (rough endoplasmic reticulum). Ribosomes are macromolecular machines for protein synthesis and those attached to RER are engaged in synthesizing proteins that will undergo post-translational modification to adapt them (in the RER lumen and within the Golgi apparatus and associated vesicles) for exposure to the oxidative extracellular environment. A key development in the evolution of the modern cell was the ability to use oxygen as an energy source. This is possible due to one organelle, the mitochondrion, whose separate genes and dual membranes suggest its origins as a symbiotic bacterium.

The key organizer of the cytoplasm, and thence of the entire cell, is the cytoskeleton (see below). This is composed of three distinct elements. Intermediate filaments are relatively stable cables of approximately 10 nm diameter that provide strength. Actin microfilaments (6–8 nm diameter) form highly branched scaffolds under the cell surface, organizing the shape of the cell surface and its specialized functions, including extracellular interactions such as signalling and adhesion, by binding to the intracellular domains of receptors and adhesive proteins, respectively. The actin scaffold under the cell surface is highly labile, forming, branching and dissolving in response to extracellular signals. Specialized myosin-family motor proteins attach to actin filaments, generating force to move membranes and to relay vesicles between the surface and the tubulin network. The tubulin network, however, is the core organizer of the cell; it is polarized, which allows motor proteins to move directionally along the tubules and convey vesicular traffic around the cell.

Endoplasmic reticulum

Endoplasmic reticulum is a system of interconnecting membrane-lined channels within the cytoplasm (Fig. 1.7). These channels take various forms, including cisternae (flattened sacs), tubules and vesicles. The membranes divide the cytoplasm into two major compartments. The intramembranous compartment includes the space where secretory products are stored or transported to the Golgi complex and cell exterior. The extramembranous cytosol is made up of the colloidal proteins such as enzymes, carbohydrates and small protein molecules, together with ribosomes and ribonucleic acids, and elements of the cytoskeleton.
Structurally, the channel system can be divided into rough or granular endoplasmic reticulum, which has ribosomes attached to its outer cytosolic surface, and smooth or agranular endoplasmic reticulum, which lacks ribosomes. Functionally, the endoplasmic reticulum is compartmentalized into specialized regions with unique functions. For further reading see Levine & Rabouille (2005).

**Rough endoplasmic reticulum**

The rough endoplasmic reticulum, studded with ribosomes, is a site of protein synthesis (Fig. 1.8). Most proteins pass through its membranes and accumulate within its cisternae, although some integral membrane proteins, e.g. plasma membrane receptors, are inserted into the rough endoplasmic reticulum membrane, where they remain. After passage from the rough endoplasmic reticulum, proteins remain in membrane-bound cytoplasmic organelles such as lysosomes, become incorporated into new plasma membrane, or are secreted by the cell. Some carbohydrates are also synthesized by enzymes within the cavities of the rough endoplasmic reticulum and may be attached to newly formed protein (glycosylation). Vesicles are budded off from the rough endoplasmic reticulum for transport to the Golgi as part of the protein-targeting mechanism of the cell.

Smooth endoplasmic reticulum

The smooth endoplasmic reticulum (Fig. 1.7) is associated with carbohydrate metabolism and many other metabolic processes, including detoxification and synthesis of lipids, cholesterol and other steroids. The membranes of the smooth endoplasmic reticulum serve as surfaces for the attachment of many enzyme
systems, e.g. the enzyme cytochrome P450, which is involved in important detoxification mechanisms and is thus accessible to its substrates, which are generally lipophilic. They also cooperate with the rough endoplasmic reticulum and the Golgi apparatus to synthesize new membranes; the protein, carbohydrate and lipid components are added in different structural compartments. Highly specialized types of endoplasmic reticulum are present in some cells. For example, in skeletal muscle cells, the smooth endoplasmic reticulum (sarcoplasmic reticulum) stores calcium ions, which are released into the cytosol to initiate contraction after stimulation initiated by a motor neurone at the neuromuscular junction (p. 62).

**Ribosomes**

Ribosomes are macromolecular machines that catalyse the synthesis of proteins from amino-acids. They are granules approximately 15 nm in diameter, composed of ribosomal RNA (rRNA) molecules assembled into two unequal subunits. A large number of proteins, mostly small and basic, are applied mainly to the surfaces of the subunit cores of RNA. The subunits can be separated by their sedimentation coefficients (S) in an ultracentrifuge, into larger 60S and smaller 40S components. These are associated with 73 different proteins (40 in the large subunit and 33 in the small), which have structural and enzymatic functions. Three small, highly convoluted rRNA strands (28S, 5.8S and 5S) make up the large subunit, and one strand (18S) is in the small subunit. Their synthesis and assembly into subunits takes place in the nucleolus, and includes association with ribosomal proteins translocated from their site of synthesis in the cytoplasm. The individual subunits are then transported into the cytoplasm, where they remain separate from each other when not actively synthesizing proteins.

A typical cell contains millions of ribosomes. They may be solitary, relatively inactive structures, or may form groups (polyribosomes or polysomes) attached to messenger RNA (mRNA), which they translate during protein synthesis. Polysomes may be attached to the membranes of the rough endoplasmic reticulum (see Fig. 1.8) or may lie free in the cytosol, where they synthesize proteins for use outside the system of membrane compartments, including enzymes of the cytosol and cytoskeletal proteins. Some of the cytosolic products include proteins that can be inserted directly into (or through) membranes of selected organelles, such as mitochondria and peroxisomes.

In a mature polysome, all the attachment sites of the mRNA are occupied as ribosomes move along it, synthesizing protein according to its nucleic acid sequence. Consequently, the number of ribosomes in a polysome indicates the length of the mRNA molecule and hence the size of the protein being made. The two subunits have separate roles in protein synthesis. The 40S subunit is the site of attachment and translation of mRNA. The 60S subunit is responsible for the release of the new protein and, where appropriate, attachment to the endoplasmic reticulum via an intermediate docking protein that directs the newly synthesized protein through the membrane into the cisternal space.

Protein synthesis on ribosomes may be suppressed by a class of RNA molecule known as small interfering RNA (siRNA) or silencing RNA. These molecules are typically 20–25 nucleotides in length and bind (as a complex with proteins) to specific mRNA molecules via their complementary sequence. This triggers the enzymatic destruction of the mRNA or prevents the movement of ribosomes along it. Synthesis
of the encoded protein is thus prevented. Their normal function may have anti-viral or other protective effects; there is also potential for developing artificial siRNAs as a therapeutic tool for silencing disease-related genes.

**Golgi apparatus (Golgi complex)**

The Golgi apparatus is a distinct cytoplasmic region near the nucleus, and is particularly prominent in secretory cells when stained with silver or other metallic salts. The Golgi apparatus forms part of the pathway by which proteins synthesized in the rough endoplasmic reticulum undergo post-translational modification and are targeted to the cell surface for secretion or for storage in membranous vesicles. As with the endoplasmic reticulum, the Golgi apparatus is compartmentalized spatially, in a labile manner, to carry out specific functions.

Ultrastructurally, the Golgi apparatus is a membranous organelle (Fig. 1.8) consisting of a stack of several flattened membranous cisternae, together with clusters of vesicles surrounding its surfaces. Seen in vertical section, it is often cup-shaped. Small transport vesicles from the rough endoplasmic reticulum, generated by a process of budding and pinching off, are received at one face of the Golgi stack, the convex *cis*-face (entry or forming surface). Here, they deliver their contents to the first cisterna in the series by membrane fusion. From the edges of this cisterna, the protein is transported to the next cisterna by vesicular budding and then fusion, and this process is repeated until the final cisterna at the concave *trans* face (exit or condensing surface) is reached. Here, larger vesicles are formed for delivery to other parts of the cell.

In addition to these cisternae, there are other membranous structures that form an integral part of the Golgi apparatus, termed the *cis*-Golgi and *trans*-Golgi networks. The *cis*-Golgi network is a region of complex membranous channels interposed between the rough endoplasmic reticulum and the Golgi *cis* face (Golgi–rough endoplasmic reticulum complex), which receives and transmits vesicles in both directions. Its function is to select appropriate proteins synthesized on the rough endoplasmic reticulum for delivery by vesicles to the Golgi stack, while inappropriate proteins are shuttled back to the rough endoplasmic reticulum.

The *trans*-Golgi network, at the other side of the Golgi stack, is also a region of interconnected membrane channels engaged in protein sorting. Here, modified proteins processed in the Golgi cisternae are packaged selectively into vesicles and dispatched to different parts of the cell. The packaging depends on the detection, by the *trans*-Golgi network, of particular amino-acid signal sequences, leading to their enclosure in membranes of appropriate composition that will further modify their contents, e.g. by extracting water to concentrate them or by pumping in protons to acidify their contents. The membranes contain specific signal proteins, which may allocate them to microtubule-based transport pathways and allow them to dock with appropriate targets elsewhere in the cell, e.g. the plasma membrane in the case of secretory vesicles. Vesicle formation and budding at the *trans*-Golgi network involves the addition of clathrin on their external surface, to form coated pits.

Within the Golgi stack proper, proteins undergo a series of sequential chemical modifications that started in the rough endoplasmic reticulum. These include: changes in glycosyl groups, e.g. removal of mannose, addition of *N*-acetyl glucosamine and
sialic acid; sulphation of attached glycosaminoglycans; protein phosphorylation. Lipids formed in the endoplasmic reticulum are also routed for incorporation into vesicles.

The role of the Golgi apparatus in the synthesis of primary lysosomes is a major activity in cells with abundant lysosomes, such as those with phagocytic roles. In glandular cells with an apical secretory zone, the Golgi apparatus lies between the secretory surface and the nucleus. In fibroblasts, there are two or more groups of Golgi stacks; up to 50 groups are found in liver cells. The Golgi apparatus is often closely associated with the centrosome (a region of the cell containing a centriole pair and related microtubules), reflecting a link with the microtubule-mediated vesicle transport system.

**Endosomes, lysosomes, proteasomes and peroxisomes**

The endosome system of vesicles originates in small endocytic vesicles (clathrin-coated vesicles and caveolae) or larger phagosomes and macropinocytic vesicles taken up by the cell from the exterior. Clathrin-dependent endocytosis occurs at specialized patches of plasma membrane called coated pits; this mechanism is also used to internalize ligands bound to surface receptor molecules and is also termed receptor-mediated endocytosis. Caveolae (little caves) are structurally distinct vesicles most widely used by endothelial and smooth muscle cells, where they are involved in transcytosis, signal transduction and possibly other functions. For further reading, see Pollard & Earnshaw (2007).

The endocytic system is linked functionally to a second series of membranous structures, the lysosomes. Lysosomes contain acid hydrolases, which process or degrade exogenous materials (heterophagy), and intracellular organelles that are exhausted, damaged or no longer required (autophagy). There is a continual exchange of vesicles between this system and the Golgi–rough endoplasmic reticulum complex, so that the endosomal/lysosomal system is provided with hydrolytic enzymes and the Golgi receives depleted vesicles for recharging. Once internalized, endocytic vesicles shed their coat of adaptin and clathrin, and fuse with a tubular cisterna termed an early endosome, where the receptor molecules release their bound ligands. Membrane and receptors from the early endosomes can be recycled to the cell surface as exocytic vesicles.

**Late endosomes**

After a brief period in the early endosomes, materials can be passed on to late endosomes, which are a more deeply placed set of tubules, vesicles or cisternae. Late endosomes receive lysosomal enzymes via vesicles (small lysosomes) transported from the Golgi apparatus. The pH of late endosomes is low (about 5.0) and this activates lysosomal acid hydrolases to degrade the endosomal contents. The products of hydrolysis are either passed through the membrane into the cytosol, or may be retained in the endosome. Late endosomes (Fig. 1.8) may grow considerably in size by vesicle fusion to form multivesicular bodies and the enzyme concentration may increase greatly to form the large, dense classic lysosomes described by de Duve (1963). However, such large organelles do not appear in all cells, perhaps because late endosomes often deal very rapidly with endocytosed material.

**Lysosomes**
Lysosomes are dense, spheroidal, membrane-bound bodies 80–800 nm in diameter (Fig. 1.8, Fig. 1.9), often with complex inclusions of material undergoing hydrolysis (secondary lysosomes). They contain acid hydrolases able to degrade a wide variety of substances. To date, more than 40 lysosomal enzymes have been described, including proteases, lipases, carbohydrases, esterases and nucleases. The enzymes are heavily glycosylated, and are maintained at a low pH by proton pumps in the lysosomal membranes.

Fig. 1.9 A, Mitochondria in human cardiac muscle. The folded cristae (arrows) project into the matrix from the inner mitochondrial membrane. B, The location of the elementary particles which couple oxidation and phosphorylation reactions.

Lysosomes are numerous in actively phagocytic cells, e.g. macrophages and neutrophil granulocytes, in which lysosomes are responsible for destroying phagocytosed bacteria. In these cells, the phagosome containing the bacterium may fuse with several lysosomes. Lysosomes are also frequent in cells with a high turnover
of organelles, e.g. exocrine gland cells and neurones. Effete organelles are targeted for demolition by a process that is not fully understood, but which results in engulfment of areas of cytoplasm, including entire organelles, in a membranous cisterna. The structure then fuses with lysosomes and the contents are rapidly degraded.

Material that has been hydrolysed within late endosomes and lysosomes may be completely degraded to soluble products, e.g. amino-acids, which are recycled through metabolic pathways. However degradation is usually incomplete, and some debris remains. A debris-laden vesicle is called a residual body or tertiary lysosome (Fig. 1.8B), and may be passed to the cell surface, where it is ejected by exocytosis; alternatively, it may persist inside the cell as an inert residual body. Considerable numbers of residual bodies can accumulate in long-lived cells, often fusing to form larger dense vacuoles with complex lamellar inclusions. As their contents are often darkly pigmented, this may change the colour of the tissue, e.g. in neurones the end-product of lysosomal digestion, lipofuscin (neuromelanin or senility pigment), gives ageing brains a brownish-yellow colouration.

Lysosomal enzymes may also be secreted – often as part of a process to alter the extracellular matrix, as in osteoclast erosion of bone (p. 88). Abnormal release of enzymes can cause tissue damage, as in certain types of arthritis. Some drugs, e.g. cortisone, can stabilize lysosomal membranes and may therefore inhibit many lysosomal activities, including the secretion of enzymes, and their fusion with phagocytic vesicles.

**Lysosomal storage diseases**

If any of the lysosomal enzymes are defective because of gene mutations, the materials that they normally degrade will accumulate within late endosomes and lysosomes. Many such lysosomal storage diseases are known, e.g. Tay–Sachs disease, in which a faulty hexosaminidase leads to the accumulation of ganglioside in neurones, causing death during childhood. In Hurler’s syndrome, failure to metabolize certain mucopolysaccharides causes the accumulation of large amounts of matrix within connective tissue, which distorts growth of many parts of the body.

**Proteasomes**

Intracellular proteolysis occurs via two pathways, one mediated via lysosomes and the other via proteasomes. Eukaryote proteasomes are non-membranous, large barrel-shaped complexes composed of about 28 distinct protein subunits which form a highly ordered ring-shaped structure (20S ring) in both the cytoplasm and the nucleoplasm. The active sites are on the inner surfaces of the barrel; terminal apertures restrict access of substrates to these sites. Proteasomes degrade proteins, including those that are misfolded and tagged for degradation by ubiquitin, and play an important role in the cleavage of intracellular antigens (e.g. those derived from viral infection) for presentation to immune system effector cells.

**Peroxisomes**

Peroxisomes are membrane-bound vacuoles 0.5–0.15 µm across, present in all nucleated cell types. They often contain dense cores or crystalline interiors composed mainly of high concentrations of the enzyme urate oxidase. Large (0.5 µm) peroxisomes are particularly numerous in hepatocytes and kidney tubule cells.
Peroxisomes are important in the oxidative detoxification of various substances taken into or produced within cells, including ethanol and formaldehyde. Oxidation is carried out by a number of enzymes, including D-amino-acid oxidase and urate oxidase, which generate hydrogen peroxide as a source of molecular oxygen. Excess amounts of hydrogen peroxide are broken down by the enzyme, catalase. Peroxisomes also oxidize fatty acid chains by β-oxidation.

The formation of peroxisomes is unusual in that they appear to be derived by the growth and fission of previously existing peroxisomes. Their internal proteins, including oxidative enzymes, are passed from the cytosol directly through channels in their membranes, rather than by packaging from the rough endoplasmic reticulum and Golgi apparatus. These features are also found in mitochondria, although peroxisomal proteins are coded for entirely in the nucleus. Genetic abnormalities in peroxisome biogenesis are seen in Zellweger syndrome, and include gene mutations in a peroxisome enzyme transporter protein. In homozygotes, this is usually fatal shortly after birth.

**Mitochondria**

Mitochondria are membrane-bound organelles (Fig. 1.9). They are the principal source of chemical energy in most cells. Mitochondria are the site of the citric acid (Krebs’, tricarboxylic acid) cycle and the electron transport (cytochrome) pathway by which complex organic molecules are finally oxidized to carbon dioxide and water. This process provides the energy to drive the production of ATP from ADP and inorganic phosphate (oxidative phosphorylation). The various enzymes of the citric acid cycle are located in the mitochondrial matrix, whereas those of the cytochrome system and oxidative phosphorylation are localized chiefly in the inner mitochondrial membrane. It is now known that in many tissues, especially smooth muscle, mitochondria also play an important role in cell signalling, especially intracellular calcium homeostasis. They are also major producers of reactive oxygen species and oxidant stress, and are involved in activation of apoptosis.

The numbers of mitochondria in a particular cell reflect its general energy requirements; e.g. in hepatocytes there may be as many as 2000, whereas in resting lymphocytes there are usually very few. Mature erythrocytes lack mitochondria altogether. Cells with few mitochondria generally rely largely on glycolysis for their energy supplies. These include some very active cells, e.g. fast twitch skeletal muscle fibres, which are able to work rapidly, but for only a limited duration. Mitochondria appear in the light microscope as long thin threads in the cytoplasm of most cells, particularly those with a high metabolic rate, e.g. secretory cells in exocrine glands. In living cells, mitochondria constantly change shape and intracellular position; they multiply by growth and fission and may undergo fusion.

In the electron microscope, mitochondria usually appear as round or elliptical bodies 0.5–2.0 µm long. Each mitochondrion is lined by an outer and an inner unit membrane, separated by a variable gap termed the intermembrane space. The lumen is surrounded by the inner membrane and contains the mitochondrial matrix. The outer membrane is smooth and sometimes attached to other organelles, particularly microtubules. The inner membrane is deeply folded to form incomplete transverse or longitudinal tubular invaginations, cristae, which create a relatively large surface area of membrane. Mitochondrial shape, and the shape and organization of the cristae,
vary with the cell type. Cristae are most numerous and complex in cells with a high metabolic rate, e.g. cardiac muscle cells. The permeabilities of the two mitochondrial membranes differ considerably: the outer membrane is freely permeable to many substances because of the presence of large non-specific channels formed by proteins (porins), whereas the inner membrane is permeable to only a narrow range of molecules. The presence of cardiolipin, a phospholipid, in the inner membrane may contribute to this relative impermeability.

The mitochondrial matrix is an aqueous environment. It contains a variety of enzymes, and strands of mitochondrial DNA with the capacity for transcription and translation of a unique set of mitochondrial genes (mitochondrial mRNAs and transfer RNAs, mitochondrial ribosomes with rRNAs). The DNA forms a closed loop, about 5 µm across; several identical copies are present in each mitochondrion. The ratio between its bases differs from that of nuclear DNA, and the RNA sequences also differ in the precise genetic code used in protein synthesis. At least 13 respiratory chain enzymes of the matrix and inner membrane are encoded by the small number of genes along the mitochondrial DNA. The great majority of mitochondrial proteins are encoded by nuclear genes and made in the cytosol, then inserted through special channels in the mitochondrial membranes to reach their destinations. Their membrane lipids are synthesized in the endoplasmic reticulum.

Mitochondrial ribosomes are smaller and quite distinct from those of the rest of the cell; they (and mitochondrial nucleic acids) resemble those of bacteria. This similarity underpins the theory that mitochondrial ancestors were oxygen-utilizing bacteria that existed in a symbiotic relationship with eukaryotic cells unable to metabolize the oxygen produced by early plants. As mitochondria are formed only from previously existing ones, it follows that all mitochondria in the body are descended from those in the cytoplasm of the fertilized ovum. It has also been shown that mitochondria are of maternal origin because the mitochondria of the sperm are not generally incorporated into the ovum at fertilization. Thus mitochondria (and mitochondrial genetic variations and mutations) are passed only through the female line.

Mitochondria are distributed within a cell according to regional energy requirements, e.g. near the bases of cilia in ciliated epithelia, in the basal domain of the cells of proximal convoluted tubules in the renal cortex (where considerable active transport occurs) and around the proximal end of the flagellum in spermatozoa. They may be involved with tissue-specific metabolic reactions, e.g. various urea-forming enzymes in liver cell mitochondria. Moreover, a number of genetic diseases of mitochondria affect particular tissues exclusively, e.g. mitochondrial myopathies (skeletal muscle) and mitochondrial neuropathies (nervous tissue). For further information see Graff et al (2002).

**Cytosolic organelles**

The aqueous cytosol surrounds the membraneous organelles described above. It also contains various non-membranous organelles, including free ribosomes, a system of filamentous proteins known as the cytoskeleton, and other inclusions, such as storage granules (e.g. glycogen) and lipid vacuoles.

**Lipid vacuoles**
Lipid vacuoles are spherical bodies of various sizes found within many cells, but are especially prominent in the adipocytes (lipocytes) of adipose connective tissue. They do not belong to the Golgi-related vacuolar system of the cell. They are not membrane bound, but are droplets of lipid suspended in the cytosol. In cells specialized for lipid storage the vacuoles reach 80 µm or more in diameter.

Lipid vacuoles are often surrounded by cytoskeletal filaments that help to stabilize them within cells and to prevent their fusion with the membranes of other organelles, including the plasma membrane. They function as stores of chemical energy, thermal insulators and mechanical shock absorbers in adipocytes. In many cells, they may represent end-products of other metabolic pathways, e.g. in steroid-synthesizing cells, where they are a prominent feature of the cytoplasm. They may also be secreted, as in the alveolar epithelium of the lactating breast.

**Cytoskeleton**

The cytoskeleton is a system of filamentous intracellular proteins of different shapes and sizes that form a complex, often interconnected, network throughout the cytoplasm. It provides mechanical support, maintains cell shape and rigidity, and enables cells to adopt highly asymmetric or irregular profiles, e.g. in neurones. The cytoskeleton plays an important part in establishing structural polarity and different functional domains within a cell. It also provides mechanical support for projections from the cell surface such as microvilli and cilia, and anchors them into the cytoplasm.

The cytoskeleton restricts specific organelles to particular cellular locations, e.g. the Golgi apparatus is near the nucleus and endoplasmic reticulum, and mitochondria are near sites of energy requirement. Most specifically, the cytoskeleton is concerned with motility, either within the cell (e.g. shuttling vesicles and macromolecules between cytoplasmic sites, or the movement of chromosomes during mitosis), or of the entire cell (e.g. in embryonic morphogenesis or the chemotactic migration of leukocytes). One of the most highly developed and specialized functions of the cytoskeleton is seen in the contractility of muscle cells.

The catalogue of cytoskeletal structural proteins is extensive and still increasing. The major filamentous structures found in non-muscle cells are microfilaments (actin), microtubules (tubulin), and intermediate filaments (assemblies of cell type-specific intermediate filament proteins). Other important components are proteins that bind to the principal filamentous types to link them together or to generate movement. These include actin-binding proteins such as myosin, which in some cells can assemble into thick filaments, and microtubule-associated proteins. Pathologies involving cytoskeletal abnormalities are reviewed in Ramaekers & Bosman (2004).

**Actin filaments (microfilaments)**

Actin filaments are flexible filaments with a width of 6–8 nm (Fig. 1.10), and a solid cross-section. Within most cell types, actin constitutes the most abundant protein and in some motile cells its concentration may exceed 200 µM (10 mg protein per ml cytoplasm). The filaments are formed by the ATP-dependent polymerization of actin monomer (with a molecular mass of 43 kDa) into a characteristic linear form in which the subunits are arranged in a single tight helix with a distance of 13 subunits between turns. The polymerized form is termed F-actin (fibrillar actin) and the unpolymerized form is G-actin (globular actin). Each monomer has an asymmetric structure. When
monomers polymerize, they confer a defined polarity on the filament: the plus end favours monomer addition, and the minus end favours monomer dissociation. Myosins bind to filamentous actin at an angle to give the appearance of a series of arrowheads pointing towards the minus end of the filament, and the barbs point towards the plus end. There is a dynamic equilibrium between G-actin and F-actin: in most cells about 50% of the actin is estimated to be in the polymerized state.

Fig. 1.10 The cytoskeleton. A, Immunofluorescence micrograph of α actin microfilaments (green) in human airway smooth muscle cells in culture. The actin-binding protein, vinculin (red), is localized at the ends of actin filament bundles; nuclei are blue. B, Immunofluorescence micrograph of keratin intermediate filaments (green) in human keratinocytes in culture. Desmosome junctions are labelled with antibody against desmoplakin (red). Nuclei are stained blue (Hoechst). By courtesy of Prof. Dr. W.W. Franke, German Cancer Research Centre, Heidelberg. C, Electron micrograph of human nerve showing microtubules (small, hollow structures in cross-section, long arrow) in a transverse section of an axon (A), engulfed by a non-myelinating Schwann cell (S). Neuronal intermediate filaments (neurofilaments) are the solid, electron-dense profiles, also in transverse section (short arrow).

Actin-binding proteins

A wide variety of actin-binding proteins are capable of modulating the form of actin within the cell. These interactions are fundamental to the organization of cytoplasm and to cell shape. Actin-binding proteins can be grouped into bundling proteins, gel-forming proteins and filament severing proteins.

Bundling proteins tie actin filaments together in longitudinal arrays to form cables or core structures. The bundles may be closely spaced, e.g. in microvilli, microspikes and filopodia, where parallel filaments are tied tightly together to form stiff bundles oriented in the same direction. Proteins with this function include fimbrin and villin (also classified as a severing protein). Other actin-bundling proteins form rather looser bundles of filaments that run anti-parallel to each other with respect to their plus and minus ends. They include myosin II, which can form cross-links with ATP-dependent motor activity, and cause adjacent actin filaments to slide on each other, and either change the shape of cells or (if the actin bundles are anchored into the cell membrane at both ends), maintain a degree of active rigidity.

Gel-forming proteins, such as filamin, interconnect adjacent actin filaments to produce loose filamentous meshworks (gels) composed of randomly orientated F-actin. These networks are frequently found in the outer cortical regions of cells, e.g. fibroblasts. They form a semi-rigid zone from which most other organelles are excluded. Severing proteins, such as gelsolin and severin, bind to F-actin filaments and sever them, which produces profound changes within the actin cytoskeleton and in its coupling to the cell surface.

Other classes of actin-binding protein link the actin cytoskeleton to the plasma membrane either directly or indirectly through a variety of membrane-associated proteins. The latter may also create links via transmembrane proteins to the extracellular matrix. Best known of these is the family of spectrin-like molecules, which can bind to actin and also to each other and various membrane-associated proteins to create supportive networks beneath the plasma membrane. Defects in such molecules are linked to a number of inherited diseases (reviewed in Bennett & Healy 2008). Spectrin is found in erythrocytes, and closely related molecules are present in many other cells; for instance, fodrin is found in nerve cells, and dystrophin occurs in muscle cells, linking the contractile apparatus with the extracellular matrix via integral membrane proteins. Proteins such as ankyrin (which also binds actin directly), vinculin, talin, zyxin and paxillin connect actin-binding proteins to integral plasma membrane proteins such as integrins (directly or indirectly), and thence to focal adhesions. Myosin I and other unconventional myosins connect actin filaments to membranous structures, including the plasma membrane and transport vesicle membranes. Tropomyosin, an important regulatory protein of muscle fibres, is also present in non-muscle cells, where its function may be primarily to stabilize actin filaments against depolymerization. For further reading see Pollard & Earnshaw (2007).

Myosins – the motor proteins

The myosin family of microfilaments is often classified within a distinct category of motor proteins. Myosin proteins have a globular head region consisting of a heavy and a light chain. The heavy chain bears an α-helical tail of varying length. The head
has an ATPase activity and can bind to and move along actin filaments – the basis for myosin function as a motor protein. The best-known class is myosin II, which occurs in muscle and in many non-muscle cells. Its molecules have two heads and two tails, intertwined to form a long rod. The rods can bind to each other to form long, thick filaments, as seen in striated and smooth muscle fibres, myoepithelial cells and myofibroblasts. Myosin II molecules can also assemble into smaller groups, especially dimers, which can cross-link individual actin microfilaments in stress fibres and other F-actin arrays. The ATP-dependent sliding of myosin on actin forms the basis for muscle contraction and the extension of microfilament bundles, as seen in cellular motility or in the contraction of the ring of actin and myosin around the cleavage furrow of dividing cells. There are a number of known subtypes of myosin II: they assemble in different ways and have different dynamic properties. In skeletal muscle the myosin molecules form bipolar filaments 15 nm thick. Because these filaments have a symmetric anti-parallel arrangement of subunits, the midpoint is bare of head regions. In smooth muscle the molecules form thicker, flattened ribbons and are orientated in different directions on either face of the ribbon. These arrangements have important consequences for the contractile force characteristics of the different types of muscle cell.

Related molecules include the myosin I subfamily of single-headed molecules with tails of varying length. Functions of myosin I include the movements of membranes in endocytosis, microspike formation in neuronal growth cones, actin–actin sliding and attachment of actin to membranes, e.g. of microvilli. Myosin V is implicated in the movements of membranous organelles on actin filaments. So, for example, vesicles track along F-actin in a similar manner to kinesin and dynein-related movements along microtubules. Other myosins have been isolated; the significance of their diversity is not fully understood.

### Other thin filaments

A heterogeneous group of filamentous structures with diameters of 2–4 nm occur in various cells. The two most widely studied forms, titin and nebulin, constitute around 13% of the total protein of skeletal muscle. They are amongst the largest known molecules, and have subunit weights of around $10^6$; native molecules are about 1 µm in length. Their repetitive bead-like structure gives them elastic properties that are important for the effective functioning of muscle, and possibly for other cells.

#### Intermediate filaments

Intermediate filaments are about 10 nm thick and formed by a heterogeneous group of filamentous proteins. They are found in different cell types and are often present in large numbers, either where structural strength is needed (Fig. 1.10B,C), or to provide scaffolding for the attachment of other structures. It is likely that more complex, non-mechanical functions of intermediate filaments, with implications for human disease, remain to be discovered (see Toivola et al 2005). Intermediate filaments of different molecular classes are characteristic of particular tissues or states of maturity. They are therefore important indicators of the origins of cells or levels of differentiation, and are of considerable value in histopathology.

Of the different classes of intermediate filaments, keratin (cytokeratin) proteins are found in epithelia, where keratin filaments are always composed of equal ratios of
types I (acidic) and II (basic to neutral) keratins. About 20 types of each of the acidic and basic/neutral keratin proteins are known. Within the epidermis, expression of keratin heterodimer combinations changes as keratinocytes mature during their transition from basal to superficial layers. Genetic abnormalities of keratins are known to affect the mechanical stability of epithelia. For example, the disease epidermolysis bullosa simplex causes lysis of epidermal basal cells and blistering of the skin after mechanical trauma. It is caused by defects in genes encoding keratins 5 and 14, which produce cytoskeletal instability and thus cellular fragility in the basal cells. When keratins 1 and 10 are affected, cells in the prickle cell layer of the epidermis lyse, and this produces the intraepidermal blistering of epidermolytic hyperkeratosis. For a review, see Porter & Lane (2003).

Vimentins occur in mesenchyme-derived cells of connective tissue, desmins in muscle cells, glial fibrillary acidic protein in glial cells, and peripherin in peripheral axons. Neurofilaments are a major cytoskeletal element in neurones, particularly in axons (Fig. 1.10C), where they are the dominant protein. They are heteropolymers of low, medium and high molecular weight neurofilament proteins; the low molecular weight form is always present in combination with either the medium- or the high-molecular weight neurofilament. Abnormal accumulations of neurofilaments (neurofibrillary tangles) are characteristic features of a number of neuropathological conditions.

Other intermediate filament proteins include nestin, a molecule resembling neurofilament protein which forms intermediate filaments in neur ectodermal stem cells in particular. Nuclear lamins are intermediate filaments that line the inner surface of the nuclear envelope of all nucleated cells. They provide a mechanical framework for the nucleus and act as attachment sites for a number of proteins that organize the chromatin at the periphery of the nucleus. They are unusual in that they form an irregular anastomosing network of filaments rather than linear bundles.

The exact manner in which intermediate filament proteins polymerize to form linear filaments is much more complex than that of tubulin or actin, and has not been fully determined. The individual intermediate filament proteins are chains with a middle α-helical region flanked on either side by non-helical domains. The proteins associate as coiled coil dimers that form short rods about 48 nm long. These assemble in pairs in a staggered antiparallel formation to form soluble tetramers, eight of which pack together laterally and twist into the rope-like 10 nm intermediate filament. The 32 α-helices in parallel give the filaments their tensile strength. However, unlike actin and myosin, the antiparallel arrangement of the dimers produces a filamentous protein with no intrinsic polarity. The non-coiled regions of the subunits project outwards as side arms that can link intermediate filaments into bundles or attach them to other structures. The existence of different combinations of subunit proteins within one filament is the basis of their functional diversity. In the living cell they have been shown to be quite dynamic structures, possibly as a result of reversible phosphorylation.

Microtubules

Microtubules are polymers of tubulin with the form of hollow, relatively rigid cylinders, approximately 25 nm in diameter and of varying length (up to 70 μm in spermatozoan flagella). They are present in most cell types, and are particularly abundant in neurones (Fig. 1.10C), leukocytes and blood platelets. They are the predominant
constituent of the mitotic spindles of dividing cells. They also form part of the structure of cilia, flagella and centrioles.

There are two major classes of tubulin: \( \alpha \)- and \( \beta \)-tubulins. Before microtubule assembly, tubulins are associated as dimers with a combined molecular mass of 100 kDa (50 kDa each). Each protein subunit is approximately 5 nm across and arranged along the long axis in straight rows of alternating \( \alpha \)- and \( \beta \)-tubulins, forming protofilaments. Typically, 13 protofilaments (the number can vary between 11 and 16), associate in a ring to form the wall of a hollow cylindrical microtubule. Each longitudinal row is slightly out of alignment with its neighbour, so that a spiral pattern of alternating \( \alpha \) and \( \beta \) subunits appears when the microtubule is viewed from the side. There is a dynamic equilibrium between the dimers and assembled microtubules: dimeric asymmetry creates polarity (\( \alpha \)-tubulins are all orientated towards the minus end, \( \beta \)-tubulins towards the plus end). Tubulin is added preferentially to the plus end; the minus end is relatively slow growing. Microtubules exhibit a dramatic behaviour, known as dynamic instability, in which growing tubules can undergo a 'catastrophe', abruptly shifting from net growth to rapid shrinkage. This can result in disappearance of the microtubule, or the catastrophe can be rescued and growth resumed. Tubulins are guanosine triphosphate (GTP)-binding proteins, and growth is accompanied by hydrolysis of GTP. This may regulate the dynamic behaviour of the tubules. Microtubule growth is initiated at specific sites known as microtubule-organizing centres, the best known of which are centrosomes, from which most cellular microtubules polymerize and basal bodies, from which cilia grow.

Various drugs (e.g. colcemid, vinblastine, griseofulvin, nocodazole) cause microtubule depolymerization by binding the soluble tubulin dimers and so shifting the equilibrium towards the unpolymerized state. Microtubule disassembly causes a wide variety of effects, including the inhibition of cell division by disruption of the mitotic spindle. Conversely, the drug taxol stabilizes microtubules and promotes abnormal microtubule assembly. This can cause a peripheral neuropathy, but taxol is widely used as an effective chemotherapeutic agent in the treatment of cancer.

Different microtubules possess varying degrees of stability, e.g. microtubules in cilia are generally unaffected by many drugs that cause microtubular demolition. There are also differences between tissues, e.g. neurones have a special tubulin subclass. Microtubule organizing centres include a specialized tubulin isoform known as \( \gamma \)-tubulin, that is essential for the nucleation of microtubule growth.

**Microtubule-associated proteins**

Various proteins that can bind to assembled tubulins may be concerned with structural properties or associated with motility. One important class of microtubule-associated proteins (MAPs) consists of proteins that associate with the plus ends of microtubules. They regulate the dynamic instability of microtubules as well as interactions with other cellular substructures. Structural MAPs form cross-bridges between adjacent microtubules or between microtubules and other structures such as intermediate filaments, mitochondria and the plasma membrane. Microtubule-associated proteins found in neurones include: MAPs 1A and 1B, which are present in neuronal dendrites and axons; MAPs 2A and 2B, found chiefly in dendrites; and tau, found only in axons. MAP 4 is the major microtubule-associated protein in many other cell types. Structural microtubule-associated proteins are implicated in microtubule formation, maintenance
and demolition, and are therefore of considerable significance in cell morphogenesis, mitotic division, and the maintenance and modulation of cell shape. Motility-associated microtubule-associated proteins are found in situations in which movement occurs over the surfaces of microtubules, e.g. the transport of cytoplasmic vesicles, bending of cilia and flagella, and some movements of mitotic spindles. They include a large family of motor proteins, the best known of which are the dyneins and kinesins. Another protein, dynamin, is involved in endocytosis. The kinetochore proteins assemble at the chromosomal centromere during mitosis and meiosis. They attach (and thus attach chromosomes) to spindle microtubules; some of the kinetochore proteins are responsible for chromosomal movements in mitotic and meiotic anaphase.

All of these microtubule-associated proteins bind to microtubules and either actively slide along their surfaces or promote microtubule assembly or disassembly. Kinesins and dyneins can simultaneously attach to membranes such as transport vesicles and convey them along microtubules for considerable distances, thus enabling selective targeting of materials within the cell. Such movements occur in both directions along microtubules. Kinesin-dependent motion is usually towards the plus ends of microtubules, e.g. from the cell body towards the axon terminals in neurones, and away from the centrosome in other cells. Conversely, dynein-related movements are in the opposite direction, i.e. to the minus ends of microtubules. Dyneins also form the arms of peripheral microtubules in cilia and flagella, where they make dynamic cross-bridges to adjacent microtubule pairs. When these tethered dyneins try to move, the resulting shearing forces cause the axonemal array of microtubules to bend, generating ciliary and flagellar beating movements. Kinesins form a large and diverse family of related microtubule-stimulated ATPases. Some kinesins are motors that move cargo, others cause microtubule disassembly, whilst still others cross-link mitotic spindle microtubules to push the two centriolar poles apart during mitotic prophase.

Centrioles, centrosomes and basal bodies

Centrioles are microtubular cylinders 0.2 µm in diameter and 0.4 µm long (Fig. 1.11). They are formed by a ring of nine microtubule triplets linked by a number of other proteins. At least two centrioles occur in all animal cells that are capable of mitotic division (eggs, which undergo meiosis instead of mitosis, lack centrioles). They usually lie close together, at right angles or, most usually, at an oblique angle to each other (an arrangement often termed a diplosome), within the centrosome, a densely filamentous region of cytoplasm at the centre of the cell. The centrosome is the major microtubule-organizing centre of most cells; it is the site at which new microtubules are formed and the mitotic spindle is generated during cell division. Centriole biogenesis is a complex process that takes more than a single cell cycle to complete. At the beginning of the S phase (DNA replication phase) of the cell cycle, a new daughter centriole forms at right angles to each separated maternal centriole. Each mother–daughter pair forms one pole of the next mitotic spindle, and the daughter centriole becomes fully mature only as the progeny cells are about to enter the next mitosis. Because centrosomes are microtubule organizing centres, they lie at the centre of a network of microtubules all of which have their minus ends proximal to the centrosome. The association of membrane vesicles with dynein motors means that certain membranes (including the Golgi apparatus) concentrate near the centrosome. This is convenient, as the microtubules provide a means of targeting Golgi vesicular
products to different parts of the cell.

**Fig. 1.11** A duplicated pair of centrioles in a human carcinoma specimen. Each centriole pair consists of a mother and daughter, oriented approximately at right angles to each other so that one is sectioned transversely (T) and the other longitudinally (L). The transversely sectioned centrioles are seen as rings of microtubule triplets (arrowed).

The microtubule-organizing centre contains complexes of γ-tubulin that nucleate microtubule polymerization at the minus ends of microtubules. Basal bodies are microtubule-organizing centres that are closely related to centrioles, and are believed to be derived from them. They are located at the bases of cilia and flagella, which they anchor to the cell surface. The outer microtubule doublets of cilia and flagella originate from two of the microtubules in each triplet of the basal body.

**Cell surface projections**
The surfaces of many different types of cell are specialized to form structures that project from the surface. These projections may permit movement of the cell itself (flagella), or of fluids across the apical cell surface (cilia), or increase the surface area available for absorption (microvilli). Infoldings of the basolateral plasma membrane also increase the area for transport across this surface of the cell. In most non-dividing epithelial cells, the centriole gives rise to a non-motile primary cilium, which has an important sensory role.

Cilia and flagella

Cilia and flagella are motile, hair-like projections of the cell surface which create currents in the surrounding fluid, movements of the cell to which they are attached, or both. Cilia occur on many internal surfaces of the body, in particular: the epithelia of most of the respiratory tract; parts of the male and female reproductive tracts; the ependyma that line the central canal of the spinal cord and ventricles of the brain. They also occur at the endings of olfactory receptors and vestibular hair cells, and, in modified form, as portions of the rods and cones of the retina. A single cell may bear many cilia, e.g. in bronchial epithelium, or only one or two. Each male gamete possesses a single flagellum 70 µm long.

A cilium or flagellum consists of a shaft (0.25 µm diameter) constituting most of its length, a tapering tip and a basal body at its base, which lies within the surface cytoplasm of the cell (Fig. 1.12). Other than at its base, the entire structure is covered by plasma membrane. The core of the cilium is the axoneme, a cylinder of nine microtubule doublets that surrounds a central pair of single microtubules (Fig. 1.12). However, there is a class of cilia (primary cilia and nodal cilia) that are composed of nine microtubule doublets and no central microtubules.
Several filamentous structures are associated with the microtubules in the shaft, e.g. radial spokes extend inwards from the outer microtubules towards the central pair. The outer doublet microtubules bear two rows of tangential dynein arms attached to the A subfibre of the doublet, which point towards the B subfibre of the adjacent doublet. Adjacent doublets are also linked by thin filaments. Other filaments partially encircle the central pair of microtubules, which are also united by ladder-like spokes.

 Movements of cilia and flagella are broadly similar. Flagella move by rapid undulation, which passes from the attached to the free end. In human spermatozoa there is an additional helical component to this motion. In cilia, the beating is planar, but asymmetric. In the effective stroke, the cilium remains stiff except at the base, where it bends to produce an oar-like stroke. The recovery stroke follows, during which the bend passes from base to tip, returning the cilium to its initial position for the next cycle. The activity of groups of cilia is usually coordinated so that the bending of one is rapidly followed by the bending of the next and so on, resulting in long travelling waves of metachronal synchrony. These pass over the tissue surface in the same direction as the effective stroke.

 When a cilium bends, the microtubules do not change in length, but slide on one another. The dynein arms of peripheral doublets slant towards the base of the cilium from their attached ends. Dynein has an ATPase activity, which causes mutual sliding of adjacent doublets by initially attaching sideways to the next pair, then swinging upwards towards the tip of the cilium. There is a group of genetic diseases (reviewed in Afzelius 2004) in which cilia beat either ineffectively or not at all, e.g. Kartagener's immotile cilia syndrome. Affected cilia exhibit various ultrastructural defects, such as a lack of dynein arms or missing spokes. Patients with this syndrome suffer various respiratory problems caused by the accumulation of particles in the lungs; males are typically sterile because of the loss of sperm motility, and 50% have an alimentary tract that is a mirror image of the usual pattern (situs inversus) – i.e. it rotates in the opposite direction during early development.
Microvilli are finger-like cell surface extensions usually 0.1 µm in diameter and up to 2 µm long (Fig. 1.13). When arranged in a regular parallel series, they constitute a striated border, as typified by the absorptive surfaces of the epithelial enterocytes of the small intestine. When they are less regular, as in the gallbladder epithelium and proximal kidney tubules, the term brush border is used.
Microvilli are covered by plasma membrane and supported internally by closely packed bundles of actin filaments linked by cross-bridges of the actin-bundling proteins, fascin and fimbrin. Other bridges composed of myosin I and calmodulin connect the filament bundles to the plasma membrane. At the tip of each microvillus, the free ends of microfilaments are inserted into a dense mass that includes the protein, villin. The actin filament bundles of microvilli are embedded in the apical cytoplasm amongst a meshwork of transversely running actin filaments stabilized by spectrin to form the terminal web, which is underlain by keratin intermediate filaments. The web is anchored laterally to the zonula adherens of the apical epithelial junctional complex. Myosin II and tropomyosin are also found in the terminal web, which may explain its contractile activity.

Microvilli greatly increase the area of cell surface (up to 40 times), particularly at sites of active absorption. In the small intestine, they have a very thick cell coat or glycocalyx, which reflects the presence of integral membrane glycoproteins, including enzymes concerned with digestion and absorption. Irregular microvilli, filopodia, are also found on the surfaces of many types of cell, particularly free macrophages and fibroblasts, where they may be associated with phagocytosis and cell motility.

Long, regular microvilli are called stereocilia, an early misnomer, as they are not motile and lack microtubules. They are found on cochlear and vestibular receptor cells, where they act as sensory transducers, and also in the absorptive epithelium of the epididymis.
NUCLEUS

The nucleus (Figs 1.1, 1.2) is generally the largest intracellular structure and is usually spherical or ellipsoid in shape, with a diameter of 3–10 µm. Histological stains used to identify nuclei in tissue sections mainly detect the acidic molecules of deoxyribonucleic acid (DNA), which are largely confined to the nucleus.

Nuclear membrane

The nucleus is surrounded by two concentric lipid bilayers which together form the nuclear membrane or envelope. The outer membrane bilayer and the lumen between the two bilayers are continuous with the rough endoplasmic reticulum. Like the rough endoplasmic reticulum, the outer membrane of the nuclear envelope is studded with ribosomes that are active in protein synthesis; the newly synthesized proteins pass into the perinuclear space between the two membrane layers.

A special class of intermediate filaments known as lamins is associated with the inner surface of the nuclear membrane. The lamins form a dense meshwork beneath the membrane, the nuclear lamina. The lamin filaments cross each other at right angles to create an irregular anastomosing network that covers the interior surface of the nuclear membrane. In so doing, they reinforce the nuclear membrane mechanically, determine the shape of the nucleus and provide a binding site for a range of proteins that anchor chromatin. Nuclear lamin A, with over 350 mutations, is the most mutated protein linked to human disease. Lamin A mutations cause a surprisingly wide range of diseases, from progeria to various dystrophies (reviewed in Mattout et al 2006 and Pollard and Earnshaw 2007).

Condensed chromatin (heterochromatin) also tends to aggregate near the nuclear membrane during interphase. At the end of mitotic and meiotic prophase (see below), the lamin filaments disassemble, causing the nuclear membranes to vesiculate and disperse into the endoplasmic reticulum. During the final stages of mitosis (telophase), proteins of the nuclear periphery, including lamins, associate with the surface of the chromosomes, providing docking sites for membrane vesicles. Fusion of these vesicles reconstitutes the nuclear compartment.

The transport of molecules between the nucleus and the cytoplasm occurs via specialized nuclear pore structures that perforate the nuclear membrane (Fig. 1.14A). They act as highly selective directional molecular filters, permitting proteins such as histones and gene regulatory proteins (which are synthesized in the cytoplasm but function in the nucleus) to enter the nucleus, and molecules that are synthesized in the nucleus but destined for the cytoplasm (e.g. ribosomal subunits, transfer RNAs and messenger RNAs), to leave the nucleus.
Ultrastructurally, nuclear pores appear as disc-like structures with an outer diameter of 130 nm and an inner pore with an effective diameter for free diffusion of 9 nm (Fig. 1.14B). The nuclear membrane of an active cell is bridged by up to 4000 such pores. The nuclear pore complex has an octagonal symmetry and is formed by an assembly of more than 50 proteins, the nucleoporins. The inner and outer nuclear membranes fuse around the pore complex (Fig. 1.14A). Nuclear pores are freely permeable to small molecules, ions and proteins up to about 17 kDa. Most proteins that enter the nucleus do so as complexes with specific transport receptor proteins known as importins. Importins shuttle back and forth between the nucleus and cytoplasm. Binding of the cargo to the importin requires a short sequence of amino acids known as a nuclear localization sequence (NLS), and can be either direct or via an adapter protein. Interactions of the importin with components of the nuclear pore move it together with its cargo through the pore by an energy-independent process still not understood. A complementary cycle functions in export of proteins and RNA molecules from the nucleus to the cytoplasm using transport receptors known as exportins. For further explanation, see Pollard & Earnshaw (2007).
Chromatin

DNA is organized within the nucleus in a DNA–protein complex known as chromatin. The protein constituents of chromatin are the histones and the non-histone proteins. Non-histone proteins are an extremely heterogeneous group that includes structural proteins, DNA and RNA polymerases and gene regulatory proteins. Histones are the most abundant group of proteins in chromatin, primarily responsible for the packaging of chromosomal DNA into its primary level of organization, the nucleosome. There are four core histone proteins: H2A, H2B, H3 and H4 that combine in equal ratios to form a compact octameric nucleosome core. A fifth histone, H1, is involved in further compaction of the chromatin. The DNA molecule (one per chromosome) winds twice around each nucleosome core, taking up 165 nucleotide pairs. This packaging organizes the DNA into a chromatin fibre 11 nm in diameter, and imparts to this form of chromatin the electron microscopic appearance of beads on a string, in which each bead is separated by a variable length of DNA, typically about 35 nucleotide pairs long. The nucleosome core region and one of the linker regions constitute the nucleosome proper, which is typically about 200 nucleotide pairs in length. However, chromatin rarely exists in this simple form and is usually packaged further into a 30 nm thick fibre, involving a single H1 histone per nucleosome, which interacts with both DNA and protein to impose a higher order of nucleosome packing. Usually, 30 nm fibres are further coiled or folded into larger domains. Individual domains are believed to decondense and extend during active transcription. In a typical interphase nucleus, euchromatin (nuclear regions that appear pale in appropriately stained tissue sections, or relatively electron-lucent in electron micrographs; Fig. 1.2) is likely to consist mainly of 30 nm fibres and loops, and contains the transcriptionally active genes. Transcriptionally active cells, such as most neurones, have nuclei that are predominantly euchromatic and often described as ‘open face’ nuclei.

Heterochromatin (nuclear regions that appear dark in appropriately stained tissue sections or electron-dense in electron micrographs) is characteristically located mainly around the periphery of the nucleus, except over the nuclear pores (Fig. 1.14A), and around the nucleolus (Fig. 1.2). It is a relatively compacted form of chromatin in which the histone proteins carry a specific set of post-translational modifications, including methylation at characteristic residues. This facilitates the binding of specific heterochromatin-associated proteins. Heterochromatin includes non-coding regions of DNA, such as centromeric regions, which are known as constitutive heterochromatin. DNA that is inactivated (becoming resistant to transcription) in some cells as they differentiate during development or cell maturation contributes to heterochromatin, and is known as facultative heterochromatin. The inactive X chromosome in females is an example of facultative heterochromatin and can be identified in the light microscope as the deeply staining Barr body (drumstick chromosome), often located near the nuclear periphery.

In transcriptionally inactive cells, chromatin is predominantly in the condensed, heterochromatic state, and may comprise as much as 90% of the total. Examples of such cells are mature neutrophil leukocytes (in which the condensed chromatin is present in a multilobed, densely staining nucleus), and the highly condensed nuclei of orthochromatic erythroblasts (late-stage erythocyte precursors). In most mature cells, a mixture of the two occurs, indicating that only a proportion of the DNA is being transcribed. A particular instance of this is seen in the mature B lymphocyte (plasma cell), in which much of the chromatin is in the condensed condition and is arranged in
regular masses around the perimeter of the nucleus, producing the so-called ‘clockface’ nucleus (Figs 4.6, 4.12). Although this cell is actively transcribing, much of its protein synthesis is of a single immunoglobulin type, and consequently much of its genome is in an inactive state.

During mitosis, the chromatin is further reorganized and condensed to form the much shortened chromosomes characteristic of metaphase. This shortening is achieved through further levels of close packing of the chromatin. The mechanism of condensation is unknown, but the condensed chromosomes are stabilized by protein complexes known as condensins. Progressive folding of the chromosomal DNA by interactions with specific proteins can reduce 5 cm of chromosomal DNA by 10,000 fold, to a length of 5 µm in the mitotic chromosome.

**Chromosomes and karyotypes**

The nuclear DNA of eukaryotic cells is organized into linear units called chromosomes. The DNA in a normal human diploid cell contains $6 \times 10^9$ nucleotide pairs organized in the form of 46 chromosomes (44 autosomes and two sex chromosomes). The largest human chromosome (number 1) contains $2.5 \times 10^8$ nucleotide pairs, and the smallest (the Y chromosome) $5 \times 10^7$ nucleotide pairs.

Each chromosomal DNA molecule contains a number of specialized nucleotide sequences that are associated with its maintenance. One is the centromere. During mitosis, a disc-shaped structure composed of a complex array of proteins, the kinetochore, forms as a substructure of the centromeric region of DNA in order to attach it to the microtubular spindle. Another sequence, the telomere, defines the end of each chromosomal DNA molecule. Telomeres consist of hundreds of repeats of the nucleotide sequence (TTAGGG)$_n$. The very ends of the chromosomes cannot be replicated by the same DNA polymerase as the rest of the chromosome, and are maintained by a specific enzyme called telomerase which contains an RNA subunit which acts as the template for lengthening the TTAGGG repeats. Thus telomerase is a specialized type of polymerase known as a reverse transcriptase that turns sequences in RNA back into DNA. The number of tandem repeats of the telomeric DNA sequence varies. It appears to shorten with successive cell divisions, because telomerase activity reduces or is absent in differentiated cells with a finite lifespan. It is believed that this mechanism contributes to regulation of cell senescence and may protect against proliferative disorders, including cancer (reviewed in Flores et al 2006).

**Classification of human chromosomes**

A number of genetic abnormalities can be directly related to the chromosomal pattern. The characterization or karyotyping of chromosome number and structure is therefore of considerable diagnostic importance. The identifying features of individual chromosomes are most easily seen during metaphase, although prophase chromosomes can be used for more detailed analyses.

Lymphocytes separated from blood samples, or cells taken from other tissues, are used as a source of chromosomes. Diagnosis of fetal chromosome patterns is generally carried out on samples of amniotic fluid containing fetal cells aspirated from the uterus by amniocentesis, or on a small piece of chorionic villus tissue removed from the placenta. Whatever their origin, the cells are cultured *in vitro* and stimulated
to divide by treatment with agents that stimulate cell division. Mitosis is interrupted at metaphase with spindle inhibitors. The chromosomes are dispersed by first causing the cells to swell in a hypotonic solution, then the cells are gently fixed and mechanically ruptured on a slide to spread the chromosomes. They are subsequently stained in various ways to allow the identification of individual chromosomes by size, shape and distribution of stain (Fig. 1.15). General techniques show the obvious landmarks, e.g. lengths of arms and positions of constrictions. Banding techniques demonstrate differential staining patterns, characteristic for each chromosome type. Fluorescence staining with quinacrine mustard and related compounds produces Q bands, and Giemsa staining (after treatment that partially denatures the chromatin) gives G bands (Fig. 1.15A). Other less widely used methods include: reverse-Giemsa staining, in which the light and dark areas are reversed (R bands); the staining of constitutive heterochromatin with silver salts (C-banding); T-banding to stain the ends (telomeres) of chromosomes. Collectively, these methods permit the classification of chromosomes into numbered autosomal pairs in order of decreasing size, from 1 to 22, plus the sex chromosomes.

**Fig. 1.15** Chromosomes from normal males, arranged as karyotypes. A, G-banded preparation; B, preparation stained by multiplex fluorescence in situ hybridization to identify each chromosome. *(By courtesy of Dr Denise Sheer, Cancer Research UK.)*

A summary of the major classes of chromosomes is given below:

<table>
<thead>
<tr>
<th>Group</th>
<th>Features</th>

Methodological advances in banding techniques improved the recognition of abnormal chromosome patterns. The use of *in situ* hybridization with fluorescent DNA probes specific for each chromosome (Fig. 1.15B) permits the identification of even very small abnormalities.

**Nucleolus**

Nucleoli are a prominent feature of an interphase nucleus (Fig. 1.2). They are the site of most of the synthesis of rRNA and assembly of ribosome subunits. Ultrastructurally, the nucleolus appears as a pale fibrillar region (non-transcribed DNA), containing dense fibrillar cores (sites of rRNA gene transcription) and granular regions (sites of ribosome subunit assembly) within a diffuse nucleolar matrix. Five pairs of chromosomes carry rRNA genes organized in clusters of tandemly repeated units on each chromosome. Each rRNA unit is transcribed individually and encodes a large precursor RNA that is processed to yield the 28S, 18S and 5.8S rRNA molecules. This processing takes place in the nucleolus, as does the processing of a number of other stable RNAs, including the RNA component of the signal recognition particle (SRP), which is essential for protein secretion. During mitosis the nucleolus breaks down. It reforms after nuclear envelope reformation in telophase, in a process associated with the onset of transcription in nucleolar organizing centres on each chromosome. The 28S, 18S and 5.8S rRNA molecules are assembled into their ribosomal subunits in the granular region of the nucleolus together with the 5S rRNA, which is not synthesized in the nucleolus. The newly formed ribosomal subunits are then translocated to the cytoplasm through the nuclear pores.
CELL DIVISION AND THE CELL CYCLE

During prenatal development, most cells undergo repeated division as the body grows in size and complexity. As cells mature, they differentiate structurally and functionally. Some cells, such as neurones, lose the ability to divide. Others may persist throughout the lifetime of the individual as replication-competent stem cells, e.g. cells in the haemopoietic tissue of bone marrow. Many stem cells divide infrequently, but give rise to daughter cells that undergo repeated cycles of mitotic division as transit (or transient) amplifying cells. Their divisions may occur in rapid succession, as in cell lineages with a short lifespan and similarly fast turnover and replacement time. Transit amplifying cells are all destined to differentiate and ultimately to die and be replaced, unlike the population of parental stem cells, which self-renews.

Patterns and rates of cell division within tissues vary considerably. In many epithelia, such as the crypts between intestinal villi, the replacement of damaged or effete cells by division of stem cells can be rapid. Rates of cell division may also vary according to demand, as occurs in the healing of wounded skin, in which cell proliferation increases to a peak and then returns to the normal replacement level (see Ch. 7). The rate of cell division is tightly coupled to the demand for growth and replacement. Where this coupling is faulty, tissues either fail to grow or replace their cells, or they can overgrow, producing neoplasms.

The cell cycle is the period of time between the birth of a cell and its own division to produce two daughter cells. It generally lasts a minimum of 12 hours, but in most adult tissues can be considerably longer, and is divided into four distinct phases, which are known as G₁, S, G₂ and M. The combination of G₁, S and G₂ phases is known as interphase. M is the mitotic phase. G₁ is the period when cells respond to growth factors directing the cell to initiate another cycle; once made, this decision is irreversible. It is also the phase in which most of the molecular machinery required to complete another cell cycle is generated. Cells that retain the capacity for proliferation, but which are no longer dividing, have entered a phase called G₀ and are described as quiescent even though they may be quite active physiologically. Growth factors can stimulate quiescent cells to leave G₀ and re-enter the cell cycle, whereas the proteins encoded by certain tumour suppressor genes (e.g. the gene mutated in retinoblastoma, Rb) block the cycle in G₁. DNA synthesis (replication of the genome) occurs during S phase, at the end of which the DNA content of the cell has doubled. During G₂, the cell prepares for division; this period ends with the onset of chromosome condensation and breakdown of the nuclear membrane. The times taken for S, G₂ and M are similar for most cell types, and occupy 6–8, 2–4 and 1–2 hours respectively. In contrast, the duration of G₁ shows considerable variation, sometimes ranging from less than 2 hours in rapidly dividing cells, to more than 100 hours within the same tissue.

Cell cycle progression is driven in part by changes in the activity of cyclin-dependent protein kinases, CDKs (protein kinases which are activated by binding of a cyclin subunit). Each cell cycle stage is characterized by the activity of one or more CDK-cyclin pairs. Transitions between cell cycle stages are triggered by highly specific proteolysis of the cyclins and other key components. The targets for proteolysis are marked for destruction by E3 ubiquitin ligases, which decorate them with polymers of
the small protein ubiquitin, a sign for recognition by the proteasome. To give one example, the transition from G2 to mitosis is driven by activation of CDK1 by its partners the A- and B-type cyclins: the characteristic changes in cellular structure that occur as cells enter mitosis are largely driven by phosphorylation of proteins by active CDK1-cyclin A and CDK1-cyclin B (further details are beyond the scope of this book). Cells exit from mitosis when the anaphase promoting complex/cyclosome (APC/C), an E3 ubiquitin ligase, marks the cyclins for destruction. The APC/C also triggers for destruction another protein whose function is to protect the cohesion between sister chromatids. An analogous process of protein phosphorylation coupled with targeted destruction drives the transition between G1 and S phase as cells commit to another cycle of proliferation.

There are important checkpoints in the cell cycle at which progress will be arrested if, for instance, DNA replication or mitotic spindle assembly and chromosome attachment are incomplete. Negative regulation systems also operate to delay cell cycle progression when DNA has been damaged by radiation or chemical mutagens. Cells with checkpoint defects, such as loss of the protein p53, which is a major negative control element in the division cycle of all cells, are commonly associated with the development of malignancy. Cells lacking one of the critical checkpoint functions are able to progress through the cycle carrying defects, thus increasing the probability that further abnormalities will accumulate in their progeny. The p53 gene is an example of a tumour suppressor gene. For further reading, see Blow & Tanaka (2005); Pollard & Earnshaw (2007).

**MITOSIS AND MEIOSIS**

Mitosis is the process that results in the distribution of identical copies of the parent cell genome to the two daughter somatic cells. In meiosis, the divisions immediately before the final production of gametes halve the number of chromosomes to the haploid number, so that at fertilization the diploid number is restored. Moreover, meiosis includes a phase in which exchange of genetic material occurs between homologous chromosomes. This allows a reassortment of genes to take place, which means that the daughter cells differ from the parental cell in both their precise genetic sequence and their haploid state. Mitosis and meiosis are alike in many respects, and differ principally in chromosomal behaviour during the early stages of cell division. In meiosis, two divisions occur in succession, without an intervening S phase. Meiosis I is distinct from mitosis, whereas meiosis II is more like mitosis.

**Mitosis**

New DNA is synthesized during the S phase of the cell cycle interphase. This means that the amount of DNA in diploid cells has doubled to the tetraploid value by the onset of mitosis, although the chromosome number is still diploid. During mitosis, this amount is halved between the two daughter cells, so that DNA quantity and chromosome number are diploid in both cells. The cellular changes that achieve this distribution are conventionally divided into four phases called prophase, metaphase, anaphase and telophase (Fig. 1.16, Fig. 1.17).
Fig. 1.16 The stages in mitosis, including the appearance and distribution of the chromosomes.
Prophase

During prophase, the strands of chromatin, which are highly extended during interphase, shorten, thicken and resolve themselves into recognizable chromosomes. Each chromosome is made up of duplicate chromatids (the products of DNA replication) joined at their centromeres. Outside the nucleus, the two centriole pairs begin to separate, and move towards opposite poles of the cell. Parallel microtubules
are assembled between them to create the mitotic spindle, and others radiate to form
the asters, which come to form the spindle poles. As prophase proceeds, the nucleoli
disappear, and the nuclear membrane suddenly disintegrates to release the
chromosomes, an event that marks the end of prophase.

**Prometaphase–metaphase**

As the nuclear membrane disappears, the spindle microtubules extend into the central
region of the cell, attaching to the chromosomes which subsequently move towards
the equator of the spindle (prometaphase). The grouping of chromosomes at the
spindle equator is called the metaphase or equatorial plate. The chromosomes,
attached at their centromeres, appear to be arranged in a ring when viewed from
either pole of the cell, or to lie linearly across this plane when viewed from above.
Cytoplasmic movements during late metaphase effect the approximately equal
distribution of mitochondria and other organelles around the cell periphery.

**Anaphase**

By the end of metaphase every chromosome consists of a pair of sister chromatids
attached to opposing spindle poles by bundles of microtubules associated with the
centromeres. The onset of anaphase begins with the proteolytic cleavage of a key
subunit of a complex known as cohesin, which holds the replicated sister chromatids
together. This cleavage releases the cohesion between sister chromatids, which each
then move towards opposite spindle poles as the microtubule bundles attached to the
centromeres shorten and move polewards. At the end of anaphase the sister
chromatids are grouped at either end of the cell, and both clusters are diploid in
number. An infolding of the cell equator begins, and deepens during telophase as the
cleavage furrow.

**Telophase**

During telophase the nuclear membranes reform, beginning with the association of
membranous vesicles with the surface of the chromosomes. Later, after the vesicles
have fused and the nuclear envelope is complete, the chromosomes decondense and
the nucleoli reform. At the same time, cytoplasmic division, which usually begins in
early anaphase, continues until the new cells separate, each with its derived nucleus.
The spindle remnant now disintegrates. While the cleavage furrow is active, a
peripheral band or belt of actin and myosin appears in the constricting zone:
contraction of this band is responsible for furrow formation.

Failure of disjunction of chromatids, so that sister chromatids pass to the same pole,
may sometimes occur. Of the two new cells, one will have more, and the other fewer,
chromosomes than the diploid number. Exposure to ionizing radiation promotes non-
disjunction and may, by chromosomal damage, inhibit mitosis altogether. A typical
symptom of radiation exposure is the failure of rapidly dividing epithelia to replace lost
cells, with consequent ulceration of the skin and mucous membranes. Mitosis can also
be disrupted by chemical agents, particularly colchicine, taxol and their derivatives.
These compounds either disassemble spindle microtubules or interfere with their
dynamics. As a result, mitosis is arrested in metaphase. Taxol and its derivatives are
widely used in the treatment of breast cancer. Colchicine is widely used for the
treatment of gout, but the mechanism is not known and may have nothing to do with
mitotic regulation.
Meiosis

There are two cell divisions during meiosis (Fig. 1.18). Details of this process differ at a cellular level for male and female lineages.
Meiosis I

Prophase I

Meiotic prophase I is a long and complex phase that differs considerably from mitotic prophase and is customarily divided into five substages, called leptotene, zygotene, pachytene, diplotene and diakinesis (see Pollard & Earnshaw 2007).

Leptotene stage

During leptotene, homologous chromosomes (maternal and paternal copies of the same chromosome), which were replicated in a preceding S phase and each consist of sister chromatids joined at the centromere (see above), locate one another within the nucleus, and the process of genetic recombination is initiated. Cytologically, chromosomes begin to condense, appearing as individual threads that are attached via their telomeres to the nuclear membrane. They often show characteristic beading throughout their length.

Zygotene stage

During zygotene, the homologous chromosomes initiate a process known as synapsis, during which they become intimately associated with one another. Synapsis may begin near the telomeres at the inner surface of the nuclear membrane, and during this stage the telomeres often cluster to one side of the nucleus (a stage known as the bouquet because the chromosomes resemble a bouquet of flowers). The pairs of synapsed homologues, also known as bivalents, are linked together by a highly structured fibrillar band, the synaptonemal complex.

The sex chromosomes also synapse during zygotene. In males, with distinct X and Y chromosomes, synapsis involves a short region of shared DNA sequence known as the pseudoautosomal region. The unpaired sex-specific regions adopt a special hypercondensed structure known as the sex vesicle.

Chromosome behaviour in meiosis is intimately linked with the process of genetic recombination. This begins during leptotene, as homologous chromosomes first locate one another at a distance. Synapsis is thought to represent the completion of recombination, as sites of genetic exchange are turned into specialized structures known as chiasmata. Chiasmata are topological ‘knots’ that hold homologous chromosomes together.

Pachytene stage

When synapsis is complete for all chromosomes, the cell is said to be in pachytene.
Each bivalent looks like a single structure, but is actually two pairs of sister chromatids held together by the synaptonemal complex. Genetic recombination is completed at this point, with sites where it has occurred (usually one per chromosome arm) appearing as nodules in the center of the synaptonemal complex.

Diplotene stage

During diplotene, the synaptonemal complex disassembles, and pairs of homologous chromosomes, now much shortened, separate except where crossing over has occurred (chiasmata). At least one chiasma forms between each homologous pair, exchanging maternal and paternal sequences, and up to five have been observed. In the ovaries, primary oocytes become diplotene by the fifth month *in utero* and each remains at this stage until the period before ovulation (up to 50 years).

Diakinesis

Diakinesis is the prometaphase of the first meiotic division. The chromosomes, still as bivalents, become even shorter and thicker. They gradually attach to the spindle and become aligned at a metaphase plate. In eggs, the spindle forms without centrosomes. Microtubules first nucleate and are stabilized near the chromosomes, and the action of various motor molecules eventually sorts them into a bipolar spindle. Perhaps surprisingly, this spindle is as efficient a machine for chromosome segregation as the spindle of mitotic cells with centrosomes at the poles.

Metaphase I

Metaphase I resembles mitotic metaphase, except that the bodies attaching to the spindle microtubules are bivalents, not single chromosomes. These become arranged so that the homologous pairs occupy the equatorial plane of the spindle. The centromeres of each pair of sister chromatids function as a single unit, facing a single spindle pole. Homologous chromosomes are pulled towards opposite spindle poles, but are held paired at the spindle midzone by chiasmata. Thus, recombination is essential for the mechanics of the meiosis I division – without it the chromosomes cannot align properly, and errors in chromosome segregation (known as non-disjunction) lead to the production of aneuploid progeny. Most human aneuploid embryos are non-viable, and this is the major cause of fetal loss (spontaneous abortion), particularly during the first trimester of pregnancy in humans. The most common form of viable aneuploid progeny in humans is Down syndrome (trisomy for chromosome 21), which is relatively rare in young mothers, but exhibits a dramatic increase with maternal age.

Anaphase and telophase I

Anaphase I of meiosis begins with the release of cohesion between the arms of sister chromatids, much as it does during mitosis. In meiosis, this ‘unties’ the topological knots of the chiasmata, and allows homologous chromosomes to separate and migrate to opposite spindle poles. As positioning of bivalent pairs is random, assortment of maternal and paternal chromosomes in each telophase nucleus is also random. Critically, sister centromeres, and thus chromatids, do not separate during anaphase I.

During meiosis I, cytoplasmic division occurs by specialized mechanisms. In females,
the division is highly asymmetric, producing one egg and one tiny cell known as a polar body. In males, the process does not go to full completion, resulting in production of spermatocytes that remain joined by small cytoplasmic bridges.

**Meiosis II**

Meiosis II commences after only a short interval during which no DNA synthesis occurs. The centromeres of sister chromatids remain paired, but rotate so that each one can face an opposite spindle pole. Onset of anaphase II is triggered by loss of cohesion between the centromeres, as it is in mitosis. This second division is more like mitosis, in that chromatids separate during anaphase, but, unlike mitosis, the separating chromatids are genetically different (the result of genetic recombination). Cytoplasmic division also occurs and thus, in the male, four haploid cells result from meiosis I and II.
As the embryo develops, its cells pass through a series of changes in gene expression, reflected in alterations of cell structure and behaviour. They begin to diversify, separating first into two main tissue arrangements, epithelium and embryonic mesenchyme, then into more restricted subtypes of tissue, until finally they mature into cells of their particular adult lineage. In this process, and in the maturation of functioning cells of the different lineages from their stem cells, there is a sequential pattern of gene expression that changes and limits the cell to a particular specialized range of activities. Such changes involve alterations in cell structure and biochemical characteristics, particularly in the types of proteins that are synthesized. At the genetic level, differentiation is based on a change in the pattern of repression and activation of the DNA sequences encoding proteins specific to that stage of development.

A cell may be committed to a particular differentiated fate without manifesting its commitment until later. Once switched in this way, cells are not usually able to revert to an earlier stage of commitment to a differentiation pathway, so that an irreversible repression of some gene sequences must have occurred. Differentiation signals include interactions between cells that are mediated by diffusible signalling molecules elaborated by one cell and detected by another, and by contact-mediated signalling (such as Delta–Notch signalling). The latter is particularly important in establishing boundaries between different cell populations in development.

Differentiation may also depend in some instances on a temporal sequence, but probably not the number of previous cell divisions. In mature tissues in which cell turnover occurs, similar mechanisms appear to ensure the final differentiation to a functional end cell. This may be linked to the presence of a physiological stimulus, e.g. B lymphocytes respond to exposure to an antigen by differentiating into plasma cells that secrete a neutralizing antibody. In other cases, particularly where a cell is part of a highly organized tissue system, more subtle mechanisms exist to ensure a balance between cell proliferation, differentiation and programmed cell death (apoptosis). This balance is disturbed when tissue is damaged and different cell types respond differently to repair the damage. Liver hepatocytes are able to revert to a functionally less well-differentiated phenotype and re-enter the cell cycle, in order to restore cell numbers and tissue mass. Other cell types (such as skeletal muscle fibres) are unable to do so and depend on the proliferation of precursor cells (stem cells) for repair. In many tissues such as skin, where normal cell turnover is continuous, wound repair includes up-regulation of proliferation in the stem cell and transit amplifying cell compartments.

There are few instances of the transdifferentiation of one differentiated cell type into another (metaplasia, see Ch. 2), but there is evidence that stem
cells in the developing embryo and in certain mature tissues (e.g. bone marrow) may have the potential to differentiate into more diverse phenotypes than was once believed. This plasticity depends on environmental cues and offers the prospect of engineering tissues for clinical therapy. For further reading, see Alberts et al (2002).

**CELL FUSION**

A small number of cell types undergo a process of fusion, the regulation of which is not well understood, as part of their normal programme of differentiation. A variable number of precursor cells fuse their plasma membranes and form syncytia, with their nuclei occupying a common cytoplasm. The best known examples are: skeletal muscle, where many hundreds of mononucleated myoblasts fuse to form a myotube which differentiates further to form the mature skeletal muscle fibre; osteoclasts (bone resorbing cells) form from the fusion of up to 30 precursor haemopoietic cells of the monocytic lineage. Such multinucleated cells do not divide. Oocyte and spermatocyte fusion initiates embryonic development, and because the gametes are haploid, mitotic division of the diploid zygote follows.

Some normal polyploid cells, which may also have more than one nucleus, arise however by a different mechanism. Cells replicate their DNA (endoreduplication) to produce a tetraploid or octaploid nucleus, or may proceed to nuclear division and become binucleate, but fail to complete cytokinesis. Liver hepatocytes, some cardiac myocytes and the superficial cells of the urinary bladder are examples.

Other examples of cell fusion are pathological and usually result from viral infection. Measles, mumps and human immunodeficiency virus (HIV) are all fusogenic. Most cells fused as a result of viral infection do not divide and die without causing adverse effects.
APOPTOSIS

Cells die as a result of either tissue injury (necrosis) or the internal activation of a ‘suicide’ programme (apoptosis) in response to extrinsic or intrinsic cues. Apoptosis (programmed cell death, regulated cell suicide) is a central mechanism controlling multicellular development. During morphogenesis, apoptosis mediates activities such as the separation of the developing digits, and has an important role in regulating the number of neurones in the nervous system (the majority of neurones die during development). Apoptosis also ensures that inappropriate or inefficient cells of the acquired immune system are eliminated.

The morphological changes exhibited by necrotic cells are very different from those seen in apoptotic cells (Fig. 1.19). Necrotic cells swell and subsequently rupture; the resulting debris may induce an inflammatory response (see Ch. 4, Ch. 7). Apoptotic cells shrink, their nuclei and chromosomes fragment, forming apoptotic bodies, and their plasma membranes undergo conformational changes that act as a signal to local phagocytes. The dead cells are removed rapidly, and as their intracellular contents are not released into the extracellular environment, inflammatory reactions are avoided; the apoptotic fragments also stimulate macrophages to release anti-inflammatory cytokines.
Apoptosis and cell proliferation are intimately coupled: several cell cycle regulators can influence both cell division and apoptosis. The signals that trigger apoptosis include withdrawal of survival factors or exposure to inappropriate proliferative stimuli. The current model of the intracellular pathway(s) that leads to apoptosis implicates permeabilization of the mitochondrial membrane, the release of cytochrome \( c \) (from the space between the inner and outer mitochondrial membranes) into the cytosol, and subsequent activation of a family of cysteine proteases known as caspases. Caspases are the intracellular mediators of apoptosis: when activated, they initiate a cascade of degradative processes targeting proteins throughout the cell. Caspase cleavage inactivates many systems that normally promote damage repair and support cell viability in general. They also activate a number of proteins which promote the death and disassembly of the cell.

Subversion of the apoptotic response is a key characteristic of many cancer cells. Thus the tumour suppressor gene \( p53 \) (which functions in cell-cycle control, regulation of apoptosis and the maintenance of genetic stability), is mutated in about 50% of all human cancers. For further details, see Pollard & Earnshaw (2007).

CHAPTER 2 – Integrating cells into tissues

Cells evolved as single, free-living organisms, but natural selection favoured more complex communities of cells, multicellular organisms, where groups of cells specialize during development to carry out specific functions for the body as a whole. This allowed the emergence of larger organisms with greater control over their internal environment and to the evolution of highly specialized organic structures such as the brain. The human body contains more than 200 different cell types, sharing the same genome but with different patterns of gene expression.

Some cells in the body are essentially migratory, but most exist as cellular aggregates in which individual cells carry out similar or closely related functions in a coordinated manner. These aggregates are termed tissues, and can be classified into a fairly small number of broad categories on the basis of their structure, function and molecular properties. On the basis of their structure, most tissues are divided into four major types: epithelia, connective or supporting tissue, muscle and nervous tissue. Epithelia are continuous layers of cells with little intercellular space, which cover or line surfaces, or have been so derived. In connective tissues, the cells are embedded in an extracellular matrix which, typically, forms a substantial and important component of the tissue. Muscle consists largely of specialized contractile cells. Nervous tissue consists of cells specialized for conducting and transmitting electrical and chemical signals and the cells that support this activity.

There is molecular evidence that this structure-based scheme of classification has validity. Thus the intermediate filament proteins (p. 15) characteristic of all epithelia are keratins; those of connective tissue are vimentins; those of muscle are desmins; and those of nervous tissue are neurofilament and glial fibrillary acidic proteins. However, cells such as myofibroblasts, neuroepithelial sensory receptors and ependymal cells of the central nervous system have features of more than one tissue type. Despite its anomalies, the scheme is useful for descriptive purposes and widely used, and will be adopted here.

In this section, two of the major tissue categories, epithelia and general connective and supporting tissues, will be described. Specialized skeletal connective tissues, i.e. cartilage and bone, together with skeletal muscle, are described in detail in Chapter 5 as part of the musculoskeletal system overview. Smooth muscle and cardiac muscle are described in Chapter 6. Nervous system tissues are described in Chapter 3. Specialized defensive cells, which also form a migrant population within the general connective tissues, are considered in more detail in Chapter 4, with blood, lymphoid tissues and haemopoiesis.

EPITHELIA

The term epithelium is applied to the layer or layers of cells that cover the body surfaces or line the body cavities that open on to it. Developmentally, epithelia are derived from all three layers of the early embryo (p. 198). The ectoderm gives rise to the epidermis, glandular tissue of the breast, cornea and the junctional zones of the buccal cavity and anal canal. The endoderm forms the epithelial lining of the alimentary canal and its glands, most of the respiratory tract and the distal parts of the urogenital tract. Mesodermal derivatives include the epithelia of the kidney, the suprarenal (adrenal) cortex and endocrine cells of the ovary and testis. These
Endocrine cells are atypical epithelia in that they differentiate from embryonic mesenchyme and, in common with endocrine cells in general, they lack a free surface that communicates with the exterior. This atypical category also includes endothelia that line blood vessels and lymphatics (p. 135), and the epithelium-like cell layers of mesodermal (and mesenchymal) origin that line internal cavities of the body and are usually classified separately as mesothelia: they line the pericardial, pleural and peritoneal cavities.

Epithelia function generally as selective barriers that facilitate, or inhibit, the passage of substances across the surfaces they cover. In addition, they may: protect underlying tissues against dehydration, chemical or mechanical damage; synthesize and secrete products into the spaces that they line; function as sensory surfaces. In this respect, many features of nervous tissue can be regarded as those of a modified epithelium and the two tissue types share an origin (p. 186) in embryonic ectoderm.

Epithelia (Fig. 2.1) are predominantly cellular and the little extracellular material they possess is limited to the basal lamina. Intercellular junctions, which are usually numerous, maintain the mechanical cohesiveness of the epithelial sheet and contribute to its barrier functions. A series of three intercellular junctions forms a typical epithelial junctional complex: in sequence from the apical surface, this consists of a tight junctional zone, an adherent (intermediate) junctional zone and a region of discrete desmosome junctions (p. 6). Epithelial cell shape is most usually polygonal and partly determined by cytoplasmic features such as secretory granules. The basal surface of an epithelium lies in contact with a thin layer of filamentous protein and proteoglycan termed the basal lamina, which is synthesized predominantly by the epithelial cells. The basal lamina is described on p. 33.

### Complex Derived Structures
- Multicellular - esocrine and endocrine glands
- Sensory structures - e.g. taste buds
- Nervous tissue - often classified separately, but retains many characteristics of its epithelial origin
- Seminiferous epithelium
Epithelia can usually regenerate when injured. Indeed, many epithelia continuously replace their cells to offset cell loss caused by mechanical abrasion (reviewed in Blanpain et al 2007). Blood vessels do not penetrate typical epithelia and so cells receive their nutrition by diffusion from capillaries of neighbouring connective tissues. This arrangement limits the maximum thickness of living epithelial cell layers. Epithelia, together with their supporting connective tissue, can often be removed surgically as one layer, which is collectively known as a membrane. Where the surface of a membrane is moistened by mucous glands it is called a mucous membrane or mucosa (p. 39), whereas a similar layer of connective tissue covered by mesothelium is called a serous membrane or serosa (p. 39).

**CLASSIFICATION**

Epithelia can be classified as unilaminar (single-layered, simple), in which a single layer of cells rests on a basal lamina, or multilaminar, in which the layer is more than one cell thick. The latter includes: stratified squamous epithelia, in which superficial cells are constantly replaced from the basal layers; urothelium (transitional epithelium), which serves special functions in the urinary tract; and other multilaminar epithelia such as those lining the largest ducts of some exocrine glands, which, like urothelium, are replaced only very slowly under normal conditions. Seminiferous epithelium is a specialized multilaminar tissue found only in the testis.

**Unilaminar (simple) epithelia**

Unilaminar epithelia are further classified according to the shape of their cells, into squamous, cuboidal, columnar and pseudostratified types. Cell shape may, in some cases, be related to cell volume. Where little cytoplasm is present, there are generally few organelles and therefore low metabolic activity and cells are squamous or low cuboidal. Highly active cells, e.g. secretory epithelia, contain abundant mitochondria and endoplasmic reticulum and are typically tall cuboidal or columnar. Unilaminar epithelia can also be subdivided into those which have special functions, such as those with cilia, numerous microvilli, secretory vacuoles (in mucous and serous glandular cells), or sensory features. Myoepithelial cells, which are contractile, are found as isolated cells associated with glandular structures, e.g. salivary and mammary glands.

**Squamous epithelium**

Simple squamous epithelium is composed of flattened, tightly apposed, polygonal cells (squares). This type of epithelium is described as tessellated when the cells have complex, interlocking borders rather than straight boundaries. The cytoplasm may in places be only 0.1 µm thick and the nucleus usually bulges into the overlying
space (Fig. 2.2A). These cells line the alveoli of the lungs, where their surface area is huge and cytoplasmic volume correspondingly large, and they form the outer capsular wall of renal corpuscles, the thin segments of the renal tubules and various parts of the inner ear. Because it is so thin, simple squamous epithelium allows rapid diffusion of gases and water across its surface; it may also engage in active transport, as indicated by the presence of numerous endocytic vesicles in these cells. Tight junctions between adjacent cells ensure that materials pass primarily through cells, rather than between them.

**Fig. 2.2**

A, Simple squamous epithelium lining the outer parietal layer (arrows) of Bowman's capsule in the renal corpuscle (RC), stained with the trichrome, MSB. Oval epithelial nuclei project into the urinary space (U), within a highly attenuated cytoplasm. B, Simple cuboidal epithelium lining a group of collecting ducts sectioned longitudinally in the renal medulla. The basement membranes are stained magenta with periodic–acid Schiff (PAS) reagent. C, Simple columnar epithelium covering the tip (off field, right) of a villus in the ileum. Tall, columnar absorptive cells with oval, vertically-orientated nuclei, bear a striated border of microvilli, just visible as a deeper-stained apical fringe. Numerous, interspersed goblet cells are present, with pale apical cytoplasm filled with mucinogen secretory granules and dark, flattened, basally-situated nuclei. D, Ciliated columnar pseudostratified epithelium in the respiratory tract, and interspersed goblet cells, with pale, mucinogen granule-filled apical cytoplasm. All human tissues.
Cuboidal and columnar epithelia

Cuboidal and columnar epithelia consist of regular rows of cylindrical cells (Fig. 2.2B, Fig. 2.2C). Cuboidal cells are approximately square in vertical section, whereas columnar cells are taller than their diameter, and both are polygonal when sectioned horizontally. Commonly, microvilli (Ch. 1) are found on their free surfaces, which considerably increases the absorptive area, e.g. in the epithelia of the small intestine (columnar cells with a striated border of very regular microvilli), the gallbladder (columnar cells with a brush border) and proximal convoluted tubules of the kidney (large cuboidal to low columnar cells with brush borders).

Ciliated columnar epithelium lines most of the respiratory tract, except for the lower pharynx and vocal folds, and it is pseudostratified (Fig. 2.2D) as far as the larger bronchioles; some of the tympanic cavity and auditory tube; the uterine tube; the efferent ductules of the testis. Submucosal mucous glands and mucosal goblet cells secrete mucus on to the luminal surface of much of the respiratory tract and cilia sweep a layer of mucus and trapped dust particles etc., from the lung towards the pharynx in the mucociliary rejection current, which clears the respiratory passages of inhaled particles. Cilia in the uterine tube assist the passage of oocytes and fertilized ova to the uterus (Ch. 77).

Some columnar cells are specialized for secretion and aggregates of such cells may be described as glandular tissue. Their apical domains (p. 4) typically contain mucus- or protein-filled (zymogen) vesicles, e.g. mucin-secreting and chief cells of the gastric epithelium. Where mucous cells lie among non-secretory cells, e.g. in the intestinal epithelium, their apical cytoplasm and its secretory contents often expand to produce a characteristic cell shape, and they are known as goblet cells (Fig. 2.2D). For further details of glandular tissue, see page 31 and for the characteristics of mucus, see page 39.

Pseudostratified epithelium

Pseudostratified epithelium is a single-layered (simple) columnar epithelium in which nuclei lie at different levels in a vertical section (Fig. 2.2D). All cells are in contact with the basal lamina throughout their lifespan, but not all cells extend through the entire thickness of the epithelium. Some constitute an immature basal cell layer of smaller cells, which are often mitotic and able to replace damaged mature cells. Migrating lymphocytes and mast cells within columnar epithelia may also give a similar, pseudostratified appearance because their nuclei are found at different depths. Much of the ciliated lining of the respiratory tract is of the pseudostratified type, and so is the sensory epithelium of the olfactory area.

Sensory epithelia

Sensory epithelia are found in special sense organs of the olfactory, gustatory and vestibulocochlear receptor systems. All of these contain sensory cells surrounded by supportive, non-receptor cells. Olfactory receptors are modified neurones, and their axons pass directly to the brain, but the other types are specialized epithelial cells that synapse with terminals of afferent (and sometimes efferent) nerve fibres.

Myoepithelial cells
Myoepithelial cells, which are also sometimes termed basket cells, are fusiform or stellate in shape (Fig. 2.3), contain actin and myosin filaments, and contract when stimulated by nervous or endocrine signals. They surround the secretory portions and ducts of some glands, e.g. mammary, lacrimal, salivary and sweat glands, and lie between the basal lamina and the glandular or ductal epithelium. Their contraction assists the initial flow of secretion into larger conduits. Myoepithelial cells are ultrastructurally similar to smooth muscle cells in the arrangement of their actin and myosin, but differ from them because they originate, like the glandular cells, from embryonic ectoderm or endoderm. They can be identified immunohistochemically on the basis of the co-localization of myofilament proteins (which signify their contractile function), and keratin intermediate filaments (which accords with their epithelial lineage).

Fig. 2.3 Stellate myoepithelial cells (M) wrapped around secretory acini in the lactating mouse mammary gland, seen in the scanning electron microscope after enzymatic depletion of extracellular matrix. Blood capillaries (C) and fibroblasts (F) are also indicated.

Multilaminar (stratified) epithelia

Multilaminar epithelia are found at surfaces subjected to mechanical damage or other potentially harmful conditions. They can be divided into those which continue to replace their surface cells from deeper layers, designated stratified squamous epithelia, and others in which replacement is extremely slow except after injury.
Stratified squamous epithelia

Stratified squamous epithelia are multilayered tissues in which the formation, maturation and loss of cells is continuous, although the rates of these processes can change, e.g. after injury. New cells are formed in the most basal layers by the mitotic division (p. 21) of stem cells and transit (or transient) amplifying cells. The daughter cells move more superficially, changing gradually from a cuboidal shape to a more flattened form and are eventually shed from the surface as a highly flattened squame. Typically, the cells are held together by numerous desmosomes to form strong, contiguous cellular sheets that provide protection to the underlying tissues against mechanical, microbial and chemical damage. Stratified squamous epithelia may be broadly subdivided into keratinized and non-keratinized types.

Keratinized epithelium

Keratinized epithelium (Fig. 2.4A) is found at surfaces that are subject to drying or mechanical stresses, or are exposed to high levels of abrasion. These include the entire epidermis and the mucocutaneous junctions of the lips, nostrils, distal anal canal, outer surface of the tympanic membrane and parts of the oral lining (gingivae, hard palate and filiform papillae on the anterior part of the dorsal surface of the tongue). Their cells, keratinocytes, are described in more detail on page 146. A distinguishing feature of keratinized epithelia is that cells of the superficial layer, the stratum corneum, are anucleate, dead, flattened squames that eventually flake off from the surface. In addition, the tough keratin intermediate filaments become firmly embedded in a matrix protein. This unusual combination of strongly coherent layers of living cells and more superficial strata made of plates of inert, mechanically robust protein complexes, interleaved with water-resistant lipid, makes this type of epithelium an efficient barrier against different types of injury, microbial invasion and water loss.
**Fig. 2.4**

A. Keratinized stratified squamous epithelium in thin skin. Pigmented melanocytes are seen in the basal layer and a few keratinocytes of the prickle cell layer also contain melanin granules. The dead, keratinized layer (K) lacks nuclei. B. Non-keratinized stratified squamous epithelium of the uterine ectocervix, stained with periodic–acid–Schiff (PAS) reagent. The basement membrane (short arrows) and superficial squames, which retain their nuclei, are PAS-positive; squames sloughing off the surface are indicated (long arrow). C. Stratified low columnar epithelium of an interlobular excretory duct of the sublingual salivary gland. D. Urothelium (transitional epithelium) lining the relaxed urinary bladder. The most superficial cells have a thickened plasma membrane due to the presence of intramembranous plaques, which give an eosinophilic appearance to the luminal surface (arrows). All human tissues.

**Non-keratinized epithelium**

Non-keratinized epithelium is present at surfaces that are subject to abrasion but protected from drying (Fig. 2.4B). These include: the buccal cavity (except for the areas noted above); oropharynx and laryngopharynx; oesophagus; part of the anal canal; vagina; distal uterine cervix; distal urethra; cornea; inner surfaces of the eyelids; the vestibule of the nasal cavities. Cells go through the same transitions in general shape as are seen in the keratinized type, but they do not fill completely with keratin or secrete glycolipid, and they retain their nuclei until they desquamate at the surface. In sites where considerable abrasion occurs, e.g. parts of the buccal cavity, the epithelium is thicker and its most superficial cells may partly keratinize, so that it is referred to as parakeratinized, in contrast to the orthokeratinized state of fully keratinized epithelium. Diets deficient in vitamin A may induce keratinization of such epithelia, and excessive doses may lead to its transformation into mucus-secreting epithelium.

**Stratified cuboidal and columnar epithelia**

Two or more layers of cuboidal or low columnar cells (Fig. 2.4C) are typical of the walls of the larger ducts of some exocrine glands, e.g. the pancreas, salivary glands and the ducts of sweat glands and they presumably provide more strength than a single layer. Parts of the male urethra are also lined by stratified columnar epithelium. The layers are not continually replaced by basal mitoses and there is no progression of form from base to surface, but they can repair themselves if damaged.

**Urothelium (urinary or transitional epithelium)**

Urothelium (Fig. 2.4D) is a specialized epithelium that lines much of the urinary tract and prevents its rather toxic contents from damaging surrounding structures. It extends from the ends of the collecting ducts of the kidneys, through the ureters (p. 1242) and bladder (p. 1250), to the proximal portion of the urethra. In males it covers the urethra as far as the ejaculatory ducts, then becomes intermittent and is finally replaced by stratified columnar epithelium in the membranous urethra. In females it
extends as far as the urogenital membrane. During development, part of it is derived from mesoderm and part from ectoderm and endoderm.

The epithelium appears to be four to six cells thick, and lines organs that undergo considerable distension and contraction. It can therefore stretch greatly without losing its integrity. In stretching, the cells become flattened, without altering their positions relative to each other, as they are firmly connected by numerous desmosomes. However, the urothelium appears to be reduced to two or three cells thick. The epithelium is called transitional because of the apparent transition between a stratified cuboidal epithelium and a stratified squamous epithelium, which occurs as it is stretched to accommodate urine, particularly in the bladder. The basal cells are basophilic, with many ribosomes, uninucleate (diploid), and are cuboidal when relaxed. More apically, they form large binucleate, or, more often, polyplloid uninucleate cells. The surface cells are largest and may even be octaploid: in the relaxed state, they typically bulge into the lumen as dome-shaped cells with a thickened, eosinophilic glycocalyx or cell coat (p. 4). Their luminal surfaces are covered by a specialized plasma membrane in which plaques of intramembranous glycoprotein particles are embedded. These plaques stiffen the membrane. When the epithelium is in the relaxed state, and the surface area of the cells is reduced, the plaques are partially internalized by the hinge-like action of the more flexible interplaque membrane regions. They re-emerge onto the surface when it is stretched.

Normally, cell turnover is very slow; cell division is infrequent and is restricted to the basal layer. However, when damaged, the epithelium regenerates quite rapidly.

**Seminiferous epithelium**

Seminiferous epithelium is a highly specialized, complex stratified epithelium. It consists of a heterogeneous population of cells that form the lineage of the spermatozoa (spermatogonia, spermatocytes, spermatids), together with supporting cells (Sertoli cells). It is described in detail in Chapter 76 (p. 1266).
GLANDS

One of the features of many epithelia is their ability to alter the environment facing their free surfaces by the directed transport of ions, water or macromolecules. This is particularly well demonstrated in glandular tissue, in which the metabolism and structural organization of the cells is specialized for the synthesis and secretion of macromolecules, usually from the apical surface. Such cells may exist in isolation amongst other non-secretory cells of an epithelium, e.g. goblet cells in the absorptive lining of the small intestine, or may form highly coherent sheets of epithelium with a common secretory function, e.g. the mucous lining of the stomach and, in a highly invaginated structure, the complex salivary glands.

Glands may be subdivided into exocrine glands and endocrine glands. Exocrine glands secrete, usually via a duct, onto surfaces that are continuous with the exterior of the body, including the alimentary tract, respiratory system, urinary and genital ducts and their derivatives, and the skin. Endocrine glands are ductless and secrete hormones directly into interstitial fluid and thence the circulatory system, which conveys them throughout the body to affect the activities of other cells. In addition to strictly epithelial glands, some tissues derived from the nervous system, including the suprarenal medulla (p. 1200) and neuro-hypophysis (p. 321), are neurosecretory.

Paracrine glandular cells are similar to endocrine cells, but their secretions diffuse locally to cellular targets in the immediate vicinity; many of these are classed as neuroendocrine cells since they secrete molecules used elsewhere in the nervous system as neurotransmitters or neuromodulators (Ch. 3). Modes of signalling by secretory cells are illustrated in Fig. 1.6.

EXOCRINE GLANDS

Types of secretory process

The mechanism of secretion varies considerably. If the secretions are initially packaged into membrane-bound vesicles, these are conveyed to the cell surface (p. 9), where they are discharged. In merocrine secretion, which is by far the most common secretory mechanism, vesicle membranes fuse with the plasma membrane to release their contents to the exterior (Fig. 2.5). Specialized transmembrane molecules in the secretory vesicle wall recognize marker proteins on the cytoplasmic side of the plasma membrane and bind to them. This initiates interactions with other proteins that cause the fusion of the two membranes and the consequent release of the vesicle contents. The stimulus for secretion varies with the type of cell, but often appears to involve a rise in intracellular calcium. Glands such as the simple sweat glands of the skin, where ions and water are actively transported from plasma as an exudate, were once classified as eccrine glands. They are now known to synthesize and secrete small amounts of protein by a merocrine mechanism, and are thus reclassified as merocrine glands.
In apocrine glands, some of the apical cytoplasm is pinched off with the contained secretions, which are stored in the cell as membrane-free droplets (Fig. 2.5). The best understood example of this is the secretion of milk fat by mammary gland cells (p. 936), in which a small amount of cytoplasm is incorporated into the plasma membrane-bound lipid globule as it is released from the cell. Larger amounts of cytoplasm are included in secretions by specialized apocrine sweat glands in the axilla and anogenital regions of the body. In some tissues there is a combination of different types of secretion, e.g. mammary gland cells secrete milk fat by apocrine secretion and milk protein, casein, by merocrine secretion.

In holocrine glands (Fig. 2.5), e.g. sebaceous glands in the skin, the cells first fill with secretory products (lipid droplets or sebum, in this instance) and then the entire cell disintegrates to liberate the accumulated mass of secretion into the duct or, more usually, hair follicle.

**Structural and functional classification**

Exocrine glands are either unicellular or multicellular. The latter may be in the form of simple sheets of secretory cells, e.g. the lining of the stomach, or may be structurally more complex and invaginated to a variable degree. Such glands (Fig. 2.5) may be
simple units or their connection to the surface may be branched. Simple unbranched tubular glands exist in the walls of many of the hollow viscera, e.g. the small intestine and uterus, whereas some simple glands have expanded, flask-like ends (acini or alveoli). Such glands may consist entirely of secretory cells, or may have a blind-ending secretory portion that leads through a non-secretory duct to the surface, in which case the ducts may modify the secretions as they pass along them.

Glands with ducts may be branched (compound), and sometimes form elaborate ductal trees. Such glands generally have acinar or alveolar secretory lobules, as in the exocrine pancreas, but the secretory units may alternatively be tubular or mixed tubulo-acinar. More than one type of secretory cell may occur within a particular secretory unit, or individual units may be specialized to just one type of secretion (e.g. serous acini of salivary glands).

Exocrine glands are also classified by their secretory products. Secretory cells in mucus-secreting or mucous glands have frothy cytoplasm and basal, flattened nuclei. They stain deeply with metachromatic stains and periodic acid–Schiff (PAS) methods that detect carbohydrate residues. However, in general (i.e. non-specific) histological preparations they are weakly stained because much of their content of water-rich mucin is extracted by the processing procedures. Secretory cells in serous glands have centrally placed nuclei and eosinophilic secretory storage granules in their cytoplasm. They secrete mainly glycoproteins (including lysozyme) and digestive enzymes.

Some glands are almost entirely mucous (e.g. the sublingual salivary gland), whereas others are mainly serous (e.g. the parotid salivary gland). The submandibular gland is mixed, in that some lobules are predominantly mucous and others serous. In some regions, mucous acini share a lumen with clusters of serous cells (seen in routine preparations as serous demilunes). Although this simple approach to classification is useful for general descriptive purposes, the diversity of molecules synthesized and secreted by glands is such that complex mixtures often exist within the same cell.
ENDOCRINE GLANDS

Endocrine glands secrete directly into connective tissue interstitial fluid and the circulation. Their cells are grouped around beds of capillaries or sinusoids (p. 133) which typically are lined by fenestrated endothelia (Ch. 6) to allow the rapid passage of macromolecules through their walls. Endocrine cells may be arranged in clusters within vascular networks, in cords between parallel vascular channels or as hollow structures (follicles) surrounding their stored secretions. In addition to the cells of specialized ductless endocrine glands (e.g. pituitary, pineal, thyroid and parathyroid), hormone-producing cells also form components of other organ systems. These include: the cells of the pancreatic islets; thymic epithelial cells; renin-secreting cells of the kidney juxtaglomerular apparatus; erythropoietin-secreting cells of the kidney; circumventricular organs; interstitial testicular (Leydig) cells; interstitial follicular and luteal ovarian cells; in pregnancy, placental cells. Some cardiac myocytes, particularly in the walls of the atria, also have endocrine functions. These are all described within the appropriate regional sections.

Isolated endocrine cells also exist scattered amongst other tissues as part of the dispersed (diffuse) neuroendocrine system (p. 56), e.g. throughout the alimentary and respiratory tracts. Neuroendocrine cells are generally situated within a mucosal epithelium and their bases often rest on the basal lamina (see below). In response to an external stimulus, they secrete their product basally into interstitial fluid. A typical neuroendocrine cell is shown in Fig. 2.6. The secretory granules vary in shape, size and ultrastructure in the different cell types, many of which take the name of their secretion, e.g. gastrin-secreting G cells of the small intestine. Neuroendocrine cells share many of their secretory products with chemical mediators (p. 47) in the nervous system.
Fig. 2.6  Electron micrograph of a neuroendocrine cell between two absorptive cells in the colon (rat tissue). Dense neurosecretory granules are seen in the basal cytoplasm, apposed to the basal lamina (arrows).  
(By courtesy of Michael Crowder.)
CONTROL OF GLANDULAR SECRETION

The activities of cells in the various tissue and organ systems of the body are tightly regulated by the coordinated activity of the endocrine and autonomic nervous systems (Ch. 15). Endocrine (and paracrine) signals (Ch. 1) reach target cells in interstitial fluid, often via blood plasma, and together with autonomic nervous signals they ensure that the body responds to normal physiological stimuli and adjusts to changes in the external environment. Hormone secretion is itself controlled in a number of ways, e.g. by neural control, regulatory feedback loops or according to various cyclical, rhythmical or pulsatile patterns of release. Endocrine glands have a rich vascular supply and their blood flow is controlled by autonomic vasomotor nerves, which can thus modify glandular activity.

Glandular activity may also be controlled directly by autonomic secretomotor fibres, which may either form synapses on the bases of gland cells (e.g. in the suprarenal medulla) or release neuromediators in the vicinity of the glands, to reach them by diffusion. Alternatively, the autonomic nervous system may act indirectly on gland cells, e.g. on neuroendocrine G cells via histamine, released neurogenically from another neuroendocrine cell in the gastric lining (Ch. 65). Such paracrine activities of neuroendocrine cells (Ch. 1) are important in the respiratory, as well as the gastrointestinal system. Circulating hormones from the adenohypophysis stimulate synthesis and secretion by target cells in many endocrine glands. Such signals, mostly detected by receptors at the cell surface and mediated by second messenger systems, may increase the synthetic activity of gland cells, and may cause them to discharge their secretions by exocytosis. Secretions from certain exocrine glandular cells are expressed rapidly from those glands by the contraction of associated myoepithelial cells (Fig. 2.3) that enclose the secretory units and smaller ducts. Myoepithelial cells may be under direct neural control, as in the salivary glands, or they may respond to circulating hormones, e.g. such cells in the mammary gland respond to the concentration of circulating oxytocin.

Feedback loops and endocrine axes

The pituitary gland, in particular the adenohypophysis, is often termed the master gland, because of its central role in endocrine physiological processes. It provides the means by which the central nervous system regulates and integrates, by non-neural mechanisms, the widespread functions of the body, including the activities of other endocrine glands and, often indirectly, exocrine glands such as the breast. Regulatory hormones from the adenohypophysis stimulate synthesis and secretion in target cells of many endocrine glands; these glands therefore respond to, in addition to generating, hormonal signals.
The hypothalamus of the brain and the adenohypophysis are central to most regulatory feedback loops within the endocrine system. Loops can be either positive or negative, e.g. the hypothalamus stimulates release of follicle stimulating hormone (FSH) by the adenohypophysis, which in turn stimulates ovarian follicular maturation and secretion of oestradiol, which acts on breast and endometrial target tissues. Oestradiol, in this case, also acts back on the adenohypophysis and hypothalamus to reinforce their function positively in a feedback loop. In contrast, hypothalamic and adenohypophysial stimulation of testicular production of testosterone, which acts on targets such as skeletal muscle, are negatively regulated in a feedback loop generated by circulating testosterone. Such negative feedback regulation is a widely utilized physiological mechanism.
BASEMENT MEMBRANE AND BASAL LAMINA

There is a narrow layer of extracellular matrix (p. 36), which stains strongly for carbohydrates, at the interface between connective and other tissues, e.g. between epithelia and their supporting connective tissues. In early histological texts this layer was termed the basement membrane. As almost all of its components are synthesized by the epithelium or other tissue (e.g. muscle), rather than the adjacent connective tissue, it will be discussed here.

Electron microscopy revealed that the basement membrane is composed of two distinct components. A thin, finely fibrillar layer, the basal lamina, is associated closely with the basal cell surface (Fig. 2.7). A variable reticular lamina of larger fibrils and glycosaminoglycans of the extracellular matrix underlies this layer and is continuous with the connective tissue proper, although it is much reduced or largely absent in some tissues, e.g. surrounding muscle fibres, Schwann cells and capillary endothelia. In other tissues, the basal lamina separates two layers of cells and there are no intervening typical connective tissue elements. This occurs in the thick basal lamina of the renal glomerular filter (p. 1238) and the basal lamina of the thin portions of the lung interalveolar septa across which gases exchange between blood and air (p. 998).

Fig. 2.7 The basal lamina as seen in an electron micrograph, underlying the basal epithelial layer of human skin. The finely fibrillar dense layer (short arrows) corresponds to the lamina densa and fine collagen fibrils (long arrows) lie in the subjacent connective tissue. These contribute to the appearance of the basement membrane in light microscope preparations stained for carbohydrate-rich structures. The cell on the left is a keratinocyte (K) with dense keratin filaments in its cytoplasm, anchoring into contacts with the basal lamina, and the cell on the right is a melanocyte (M).

The basal lamina is usually about 80 nm thick, varying between 40 and 120 nm, and consists of a sheet-like fibrillar layer, the lamina densa (20–50 nm wide), separated from the plasma membrane of the cell it supports by a narrow electron-lucent zone, the lamina lucida. The lamina lucida is absent from tissues prepared by rapid freezing and so may be an artefact. In many tissues this zone is crossed by integral plasma
membrane proteins, e.g. keratinocyte hemidesmosomes (Chs 1 and 7) are anchored into the lamina densa in the basal lamina of the epidermis. The basal lamina is a delicate felt-like network composed largely of two glycoprotein polymers, laminin and type IV collagen, which self-assemble into two-dimensional sheets interwoven with each other. Early embryonic basal lamina is formed only of the laminin polymer. Two other molecules cross-link and stabilize the network: entactin (nidogen) and perlecan (a large heparan sulphate proteoglycan).

Although all basal laminae have a similar form, their thickness and precise molecular composition vary between tissues and even within a tissue, e.g. between the crypts and villi of the small intestine. The isoforms of laminin and collagen type IV differ in various tissues, thus Schwann cells and muscle cells express laminin-2 (merosin) rather than the prototypical laminin-1. Laminin-5, although not itself a basal lamina component, is found in the hemidesmosomes of the basal epidermis and links the basal lamina with epidermal transmembrane proteins, \( \alpha_6 \beta_4 \) integrin and collagen type XVII (formerly known as bullous pemphigoid antigen, one of the targets of the autoimmune blistering skin disease, bullous pemphigoid). The particular isoform of collagen type IV in the basal lamina of different tissues is reflected in tissue-specific disease patterns. Mutations in a collagen expressed by muscle and kidney glomeruli cause Alport's syndrome, a form of renal failure. Renal failure also occurs in Goodpasture's syndrome, in which renal basal lamina collagen is targeted by autoantibodies.

In Descemet's membrane in the cornea, collagen type VIII replaces collagen type IV in the much thickened (increasing with age, up to 10 \( \mu \text{m} \)) endothelial basal lamina. The basal lamina of the neuromuscular junction (p. 62) contains agrin, a heparan sulphate proteoglycan, which plays a part in the clustering of muscle acetylcholine receptors in the plasma membrane at these junctions.

**RETICULAR LAMINA**

The reticular lamina consists of a dense extracellular matrix that contains collagen. In skin, it contains fibrils of type VII collagen (anchoring fibrils), which bind the lamina densa to the adjacent connective tissue. The high concentration of proteoglycans in the reticular lamina is responsible for the positive reaction of the entire basement membrane to stains for carbohydrates, seen in sections prepared for light microscopy.
FUNCTIONS OF BASAL LAMINA

Basal laminae perform a number of important roles (Iozzo 2005). They form selectively permeable barriers (anionic filters) between adjacent tissues, e.g. in the glomerular filter of the kidney; they anchor epithelial and connective tissues and so stabilize and orientate the tissue layers; they may exert instructive effects on adjacent tissues, and so determine their polarity, rate of cell division, cell survival etc.; they regulate angiogenesis. In addition, they may act as pathways for the migration and pathfinding of growing cell processes, both in development and in tissue repair, e.g. in guiding the outgrowth of axons and the reestablishment of neuromuscular junctions during regeneration after injury in the peripheral nervous system. Changes in basal lamina thickness are often associated with pathological conditions, e.g. the thickening of the glomerular basal lamina in glomerulonephritis and diabetes.
CONNECTIVE AND SUPPORTING TISSUES

The connective tissues are defined as those composed predominantly of intercellular material, the extracellular matrix, which is secreted mainly by the connective tissue cells. The cells are therefore usually widely separated by their matrix, which is composed of fibrous proteins and a relatively amorphous ground substance (Fig. 2.8). Many of the special properties of connective tissues are determined by the composition of the matrix, and their classification is also largely based on its characteristics. In some types of connective tissue, the cellular component eventually dominates the tissue, even though the tissue originally has a high matrix:cell ratio, e.g. adipose tissue. Connective tissues are derived from embryonic mesoderm or, in the head region, largely from neural crest.

Connective tissues have several essential roles in the body. These may be subdivided into structural roles, which largely reflect the special mechanical properties of the extracellular matrix components, and defensive roles, in which the cellular component has the dominant role. Connective tissues often also play important trophic and morphogenetic parts in organizing and influencing the growth and differentiation of surrounding tissues, e.g. in the development of glands from an epithelial surface.

Structural connective tissues are divided into ordinary (or general) types, which are widely distributed, and special skeletal types, i.e. cartilage and bone, which are

![Fig. 2.8 General loose connective tissue (human), with bundles of collagen fibres (C) within an amorphous ground substance, penetrated by blood vessels (V), lymphatics and nerves. A small autonomic ganglion is arrowed.](image)
described in Chapter 5. A third type, haemolymphoid tissues, consists of peripheral
blood cells, lymphoid tissues and their precursors; these tissues are described in
Chapter 4. They are often grouped with other types of connective tissue, because of
their similar mesenchymal origins and because the various defensive cells of the
blood also form part of a typical connective tissue cell population. They reach
connective tissues via the blood circulation and migrate into them through the
endothelial walls of vessels.

CELLS OF GENERAL CONNECTIVE TISSUES

Cells of general connective tissues can be separated into the resident cell population
(fibroblasts, adipocytes, mesenchymal stem cells, etc.) and a population of migrant
cells with various defensive functions (macrophages, lymphocytes, mast cells,
neutrophils and eosinophils), which may change in number and moderate their
activities according to demand. Embryologically, fibroblasts and adipocytes arise from
mesenchymal stem cells, some of which may remain in the tissues to provide a
source of replacement cells postnatally. As noted above, the cells of haemopoietic
origin migrate into the tissue from bone marrow and lymphoid tissue.

Resident cells

Fibroblasts

Fibroblasts are usually the most numerous resident cells. They are flattened and
irregular in outline, with extended processes, and in profile they appear fusiform or
spindle-shaped (Fig. 2.9; see also Fig. 2.11). Fibroblasts synthesize most of the
extracellular matrix of connective tissue (Fig. 2.9); accordingly they have all the
features typical of cells active in the synthesis and secretion of proteins. Their nuclei
are relatively large and euchromatic and possess prominent nucleoli. In young, highly
active cells, the cytoplasm is abundant and basophilic (reflecting the high
concentration of rough endoplasmic reticulum), mitochondria are abundant and
several sets of Golgi apparatus are present. In old and relatively inactive fibroblasts
(often termed fibrocytes) the cytoplasmic volume is reduced, the endoplasmic
reticulum is sparse and the nucleus is flattened and heterochromatic.
Fig. 2.9 Electron micrograph of a fibroblast in human connective tissue, surrounded by bundles of finely banded collagen fibrils (shown at high magnification in the insert) which they secrete.
Fibroblasts are usually adherent to the fibres of the matrix (collagen and elastin), which they lay down. In some highly cellular structures, e.g. liver, kidney and spleen, and in most lymphoid tissue, fibroblasts and delicate collagenous fibres (type III collagen; reticular fibres) form fibrocellular networks which are often called reticular tissue. The fibroblasts may then be termed reticular cells or reticulocytes.

Fibroblasts are particularly active during wound repair (Ch. 7) following traumatic injury or inflammation, when tissue mass is lost through cell death. They proliferate and lay down a fibrous matrix that becomes invaded by numerous blood vessels (granulation tissue). Contraction of wounds is at least in part caused by the shortening of specialized contractile fibroblasts (myofibroblasts) with smooth muscle-like properties, which differentiate from fibroblasts in granulation tissue (reviewed in McAnulty 2007). In cases where the specialized cells of the damaged region cannot divide and regenerate functional tissue, e.g. cardiac muscle cells after infarction, connective tissue fibroblasts and their extracellular matrix fill the void to form a scar. An exception is the central nervous system, where glial scars are formed. Fibroblast activity is influenced by various factors such as steroid hormone concentrations, dietary content and prevalent mechanical stresses. In vitamin C deficiency, there is an impairment of collagen formation.

**Adipocytes (lipocytes, fat cells)**

Adipocytes occur singly or in groups in many, but not all, connective tissues. They are numerous in adipose tissue (Fig. 2.10). Individually, the cells are oval or spherical in shape, but when packed together they are polygonal. They vary in diameter, averaging 50 µm. Each cell consists of a peripheral rim of cytoplasm, in which the nucleus is embedded, surrounding a single large central globule of fat, which consists of glycerol esters of oleic, palmitic and stearic acids. There is a small accumulation of...
cytoplasm around the nucleus, which is oval in shape and compressed against the cell membrane by the lipid droplet, as is the Golgi complex. Many cytoskeletal filaments, some endoplasmic reticulum and a few mitochondria lie around the lipid droplet, which is in direct contact with the surrounding cytoplasm and not enclosed within a membrane. In sections of tissue not specially treated to preserve lipids, the lipid droplet is usually dissolved out by the solvents used in routine preparations, so that only the nucleus and the peripheral rim of cytoplasm surrounding a central empty space remain.

In neonates, a special form of adipose tissue known as brown fat is present in the interscapular region and may be more widespread. Brown fat is characterized by the presence of a large cell type in which the fat is present as several separate droplets (multilocular adipose tissue) and not as a single globule (typical of unilocular adipose tissue), and the mitochondria have unusually large and numerous cristae. These deposits of fat are concerned with heat production, mediated by mitochondria.

The mobilization of fat is under nervous or hormonal control: noradrenaline (norepinephrine) released at sympathetic nerve endings in adipose tissue is particularly important in this respect. No new adipose tissue is formed after the immediate postnatal period and accumulation of body fat, as in obesity, is due to excessive accumulation of lipid in existing adipocytes, which become very large. Conversely, weight loss results from the mobilization and metabolism of lipid from adipocyte stores, with the consequent shrinkage of the cells.

Fig. 2.10  Adipose tissue (human). Adipocytes (A) are distended polygonal cells filled with lipid, which has been extracted by the tissue processing. This leaves only the plasma membranes with scant cytoplasm and nuclei (arrows), occasionally visible compressed against the cell periphery. Small blood vessels (B) penetrate the adipose tissue.
**Mesenchymal stem cells**

Mesenchymal stem cells are normally inconspicuous cells in connective tissues. They are derived from embryonic mesenchyme and are able to differentiate into the mature cells of connective tissue during normal growth and development, in the turnover of cells throughout life and, most conspicuously, in the repair of damaged tissues in wound healing (p. 162). There is evidence that, even in mature tissues, mesenchymal stem cells remain pluripotent and able to give rise to all the resident cells of connective tissues in response to local signals and cues.

**Migrant cells**

**Macrophages**

Macrophages are typically numerous in connective tissues (Fig. 2.11), where they are either attached to matrix fibres or are motile and migratory. They are relatively large cells, 15–20 µm in diameter, with indented and relatively heterochromatic nuclei and a prominent nucleolus. Their cytoplasm is slightly basophilic, contains many lysosomes (p. 12) and typically has a foamy appearance under the light microscope. Macrophages are important phagocytes, and form part of the mononuclear phagocyte system (p. 78). They can engulf and digest particulate organic materials, such as bacteria, and are also able to clear dead or damaged cells from a tissue. They are also the source of a number of secreted cytokines that have profound effects on many other cell types. Macrophages are able to proliferate in connective tissues to a limited extent, but are derived and replaced primarily from haemopoietic stem cells (p. 75) in the bone marrow, which circulate in the blood as monocytes before migrating through vessel walls into connective tissues.

Many properties of macrophages in general connective tissue are similar to those of related cells in other sites. These include: circulating monocytes, from which they are derived; alveolar macrophages in the lungs; phagocytic cells in the lymph nodes, spleen and bone marrow; Kupffer cells of the liver sinusoids; microglial cells of the central nervous system.

**Lymphocytes**

Lymphocytes are typically present in small numbers and are numerous in general connective tissue only in pathological states, when they migrate in from adjacent lymphoid tissue or from the circulation. The majority are small cells (6–8 µm) with highly heterochromatic nuclei, but they enlarge when stimulated. Two major functional classes exist, termed B and T lymphocytes (p. 70). B lymphocytes originate in the bone marrow, then migrate to various lymphoid tissues, where they proliferate. When antigenically stimulated, they undergo further mitotic divisions, then enlarge as they mature, commonly in general connective tissues, to form plasma cells that synthesize and secrete antibodies (immunoglobulins). Mature plasma cells are rounded or ovoid, up to 15 µm across, and have an extensive rough endoplasmic reticulum. Their nuclei are spherical, often eccentrically situated and have a characteristic ‘clock-face’ configuration of heterochromatin (see p. 70 and Fig. 4.12) that is regularly distributed in peripheral clumps. The prominent Golgi complex is visible with a light microscope as a pale region to one side of the nucleus and the remaining cytoplasm is deeply basophilic because of the abundant endoplasmic reticulum. Mature plasma cells do not divide.
T lymphocytes originate from precursors in bone marrow haemopoietic tissue, but later migrate to the thymus, where they develop T-cell identity, before passing into the peripheral lymphoid system where they continue to multiply. When antigenically stimulated, T cells enlarge and their cytoplasm becomes filled with free polysome clusters. The functions of T lymphocytes are numerous: different subsets recognize and destroy virus-infected cells, tissue and organ grafts, or interact with B lymphocytes and several other defensive cell types (p. 71).

**Mast cells**

Mast cells are important defensive cells which occur particularly in loose connective tissues and often in the fibrous capsules of certain organs such as the liver. They are characteristically numerous around blood vessels and nerves. Mast cells are round or oval, approximately 20 µm in diameter, with many filopodia extending from the cell surface. The nucleus is centrally placed and relatively small, and is surrounded by large numbers of prominent vesicles and a well developed Golgi apparatus, but scant endoplasmic reticulum. The vesicles have a high content of glycosaminoglycans and show a strongly positive reaction with the periodic acid–Schiff (PAS) stain for carbohydrates. The vesicles, which are membrane-bound, vary in size and shape (mean diameter 0.5 µm) and also have a rather heterogeneous content of dense, lipid-containing material, which may be finely granular, lamellar or in the form of membranous whors.

The major granule components, many of them associated with inflammation, are the proteoglycan heparin, histamine, tryptase, superoxide dismutase, aryl sulphatase, β-hexosaminidase and various other enzymes, together with chemotactic factors for neutrophil and eosinophil granulocytes. Mast cells may be disrupted to release some or all of their contents, either by direct mechanical or chemical trauma, or after contact with particular antigens to which the body has previously been exposed. The consequences of granule release include alteration of capillary permeability, smooth muscle contraction, and activation and attraction to the locality of various other defensive cells. Responses to mast cell degranulation may be localized, e.g. urticaria, or there may occasionally be a generalized response to the release of large amounts of histamine into the circulation (anaphylactic shock). Mast cells closely resemble basophil granulocytes of the general circulation but are thought to develop as distinct descendants of an earlier myeloid lineage precursor (Ch. 4). It is believed that they are generated in the bone marrow and circulate to the tissues as immature basophil-like cells, migrating through the capillary and venule walls to their final destination. For further reading, see Bischoff (2007).

**Granulocytes (polymorphonuclear leukocytes)**

Neutrophil and eosinophil granulocytes are immigrant cells from the circulation. Relatively infrequent in normal connective tissues, their numbers may increase dramatically in infected tissues, where they are important components of cellular defence. Neutrophils are highly phagocytic, especially towards bacteria. The functions of eosinophils are less well understood. These cells are described further in Chapter 4.
CELLS OF SPECIALIZED CONNECTIVE TISSUES

Skeletal tissues, namely cartilage and bone, are generally classified with the connective tissues, but their structure and functions are highly specialized; they are described in Chapter 5. As with the general connective tissues, these specialized types are characterized by their extracellular matrix, which forms the major component of the tissues and is responsible for their properties. The resident cells are different from those in general connective tissues. Cartilage is populated by chondroblasts, which synthesize the matrix, and by mature chondrocytes. Bone matrix is elaborated by osteoblasts. Their mature progeny, osteocytes, are embedded within the matrix, which they help to mineralize, turn over and maintain. A third cell type, the osteoclast, has a different lineage origin and is derived from haemopoietic tissue; osteoclasts are responsible for bone degradation and remodelling in collaboration with osteoblasts.
EXTRACELLULAR MATRIX

The term extracellular matrix is applied collectively to the extracellular components of connective and supporting tissues. Essentially it consists of a system of insoluble protein fibres, adhesive glycoproteins and soluble complexes composed of carbohydrate polymers linked to protein molecules (proteoglycans and glycosaminoglycans), which bind water. The extracellular matrix distributes the mechanical stresses on tissues and also provides the structural environment of the cells embedded in it, forming a framework to which they adhere and on which they can move (reviewed in Even-Ram & Yamada 2005). With the exception of bone matrix, it provides a highly hydrated medium, through which metabolites, gases and nutrients can diffuse freely between cells and the blood vessels traversing it or, in the case of cartilage, passing nearby. There are many complex interactions between connective tissue cells and the extracellular matrix. The cells continually synthesize, secrete, modify and degrade extracellular matrix components, and themselves respond to contact with the matrix in the regulation of cell metabolism, proliferation and motility. Tissue remodelling depends on the controlled degradation of extracellular matrix by secreted metalloproteinases (reviewed in Mott & Werb 2004), regulated by their specific inhibitors, as occurs for instance during wound healing and involution, e.g. of the postpartum uterus. Pathological, uncontrolled degradation of matrix can lead to disease states such as emphysema and arthritis. In the process of matrix degradation, bioactive peptides are liberated that act as growth factors, cytokines and other signalling molecules to change the behaviour of cells in the vicinity.

The insoluble fibres are mainly of two types of structural protein: members of the collagen family, and elastin (Fig. 2.12). The interfibrillar matrix (ground substance) includes a number of adhesive glycoproteins that perform a variety of functions in connective tissues, including cell–matrix adhesion and matrix–cell signalling. These glycoproteins include fibronectin, laminin, tenascin and vitronectin, in addition to a number of other less well characterized proteins. The glycosaminoglycans of the interfibrillar matrix are, with one notable exception, post-translationally modified proteoglycan molecules in which long polysaccharide side chains are added to short core proteins during transit through the secretory pathway between the rough endoplasmic reticulum and the trans-Golgi network. The exception, the polymeric disaccharide, hyaluronan, has no protein core and is synthesized entirely by cell surface enzymes. For further reading on extracellular matrix molecules, see Pollard and Earnshaw (2007). Functional attributes of connective tissues vary and depend on the abundance of its different components. Collagen fibres resist tension, whereas elastin provides a measure of resilience to deformation by stretching. The highly hydrated, soluble polymers of the interfibrillar material (proteoglycans and glycosaminoglycans, mainly hyaluronan) generally form a stiff gel resisting compressive forces. Thus tissues that are specialized to resist tensile forces (e.g. tendons) are rich in collagen fibrils, tissues that accommodate changes in shape and volume (e.g. mesenteries) are rich in elastic fibres and those that absorb compressive forces (e.g. cartilages) are rich in glycosaminoglycans and proteoglycans. In bone, mineral crystals take the place of most of the soluble polymers, and endow the tissue with incompressible rigidity.
Collagens make up a very large proportion (approximately 30%) of all the proteins of the body. They consist of a wide range of related molecules that have various roles in the organization and properties of connective (and some other) tissues. The first collagen to be characterized was type I, the most abundant of all the collagens and a constituent of the dermis, fasciae, bone, tendon, ligaments, blood vessels and the sclera of the eyeball. The characteristic collagen of cartilage and the vitreous body of the eye, with a slightly different chemical composition, is type II, whereas type III is present in several tissues, including the dermis and blood vessels, and type IV is in basal lamina. The other types are widely distributed in various tissues. Five of the collagens, types I, II, III, V and XI, form fibrils; types IV, VIII and X form sheets or meshworks; types VI, VII, IX, XII, XIV and XVIII have an anchoring or linking role; types XIII and XVII are transmembrane proteins.

Biochemically, all collagens have a number of features in common. Unlike most other proteins, they contain high levels of hydroxyproline and all are composed of three polypeptides that form triple helices and are substantially modified post-translationally. After secretion, individual molecules are further cross-linked to form stable polymers. Functionally, collagens are structural proteins with considerable mechanical strength. Just a few of their distinguishing structural features are described below. For further reading on the molecular structure and functions of the collagens, see Pollard and Earnshaw (2007).
**Type I collagen**

Type I collagen is very widely distributed. It forms inextensible fibrils in which collagen molecules (triple helices) are aligned side by side in a staggered fashion, with three-quarters of the length of each molecule in contact with neighbouring molecules. The fibril has well-marked bands of charged and uncharged amino-acids arranged across it; these stain with heavy metals in a banding pattern that repeats every 65 nm in longitudinal sections viewed in the electron microscope (Fig. 2.9 insert).

Fibril diameters vary between tissues and with age. Developing tissues often have thinner fibrils than mature tissues. Corneal stroma fibrils are of uniform and thin diameter, whereas tendon fibrils may be up to 20 times thicker and quite variable. Tissues in which the fibrils are subject to high tensile loading tend to have thicker fibrils. Thick fibrils are composites of uniform thin fibrils with a diameter of 8–12 nm. The fibrils themselves are relatively flexible, but when mineralized (as in bone) or surrounded by high concentrations of proteoglycan (as in cartilage), the resulting fibre-reinforced composite materials are rigid.

Fresh type I collagen fibres are tightly packed assemblies of parallel fibrils and are white and glistening. They form variably wavy (crimped) bundles of various sizes that are generally visible at the light microscope level. The component fibres may leave one bundle and interweave with others. In some situations, collagen fibrils are laid down in precise geometrical patterns, in which successive layers alternate in direction, e.g. corneal stroma, where the high degree of order is essential for transparency. Tendons, aponeuroses and ligaments are also highly ordered tissues (Ch. 5).

**Types II, III, V and XI collagens**

Types II, III, V and XI collagens can also aggregate to form linear fibrils. Type II collagen occurs in extremely thin (10 nm) short fibrils in the vitreous humour and in very thick fibrils in ageing human cartilage. The amino-acid sequence and banding pattern are very similar to those of type I collagen, as are the post-translational modifications of the triple helical protein molecule. The fine fibrils in the vitreous may fuse into thicker aggregates in older tissue.

Type III collagen is very widely distributed, particularly in young and repairing tissues. It usually co-localizes with type I collagen, and covalent links between Type I and Type III collagen have been demonstrated. In skin, many fibrils are probably composites of Types I and III collagens.

**Reticular fibres**

Fine branching and anastomosing reticular fibres form the supporting mesh framework of many glands, including the liver (Fig. 2.13), the kidney and lymphoreticular tissue (lymph nodes, spleen, etc.). Classically, these fibres stained intensely with silver salts, although they are poorly stained using conventional histological techniques. They associate with basal laminae and are often found in the neighbourhood of collagen fibre bundles. Reticular fibres are formed principally of type III collagen.
Elastin

Elastin is a 70 kDa protein, rich in the hydrophobic amino-acids valine and alanine. Elastic fibrils, which also contain fibrillin, are highly cross-linked via two elastin-specific amino-acids, desmosine and iso-desmosine, which are formed extracellularly from...
lysine residues. They are less widely distributed than collagen, yellowish in colour, typically cross-linked and are usually thinner (10–20 nm) than collagen fibrils. They can be thick, e.g. in the ligamenta flava and ligamentum nuchae. Unlike collagen type I, they show no banding pattern in the electron microscope. They stain poorly with routine histological stains, but are stained with orcein-containing preparations (see Fig. 2.12). They sometimes appear as sheets, as in the fenestrated elastic lamellae of the aortic wall. Elastin-rich structures stretch easily with almost perfect recoil, although they tend to calcify with age and lose elasticity. Elastin is highly resistant to attack by acid and alkali, even at high temperatures.

**Interfibrillar matrix**

**Glycosaminoglycans**

The structural soluble polymers characteristic of the extracellular matrix are the acidic glycosaminoglycans, which are unbranched chains of repeating disaccharide units, each unit carrying one or more negatively charged groups (carboxylate or sulphate esters, or both). The anionic charge is balanced by cations (Na+, K+, etc.) in the interstitial fluid. Their polyanionic character endows the glycosaminoglycans with high osmotic activity, which helps keep the fibrils apart, confers stiffness on the porous gel that they collectively create and gives the tissue a varying degree of basophilia. Glycosaminoglycans are named according to the tissues in which they were first found, e.g. hyaluronan (vitreous body), chondroitins (cartilage), dermatan (skin), keratan (cornea), heparan (liver). This terminology is no longer relevant, as most glycosaminoglycans are very widely distributed, whereas, conversely, some corneas contain little or no keratan sulphate. Of the glycosaminoglycans, all except hyaluronan have short protein cores and are highly variable in their carbohydrate side chain structure.

**Hyaluronan**

Hyaluronan was formerly called hyaluronic acid (or hyaluronate, as only the salt exists at physiological pH). It is a very large, highly hydrated molecule (25,000 kDa). Hyaluronan is found in all extracellular matrices and in most tissues and is a prominent component of embryonic and developing tissues.

Hyaluronan is important in the aggregation of proteoglycans and link proteins that possess specific hyaluronan binding sites (e.g. laminin). Indeed, the very large aggregates that are formed may be the essential compression-resisting units in cartilage. Hyaluronan also forms very viscous solutions, which are probably the major lubricants in synovial joints. Because of its ability to bind water, it is often present in semi-rigid structures (e.g. vitreous humour in the eye), where it co-operates with sparse but regular meshworks of thin collagen fibrils.

**Proteoglycans**

Proteoglycans have been classified according to the size of their protein core: their nomenclature is under review. The same core protein can bear different glycosaminoglycan side chains in different tissues. The functions of many proteoglycans are poorly understood. Some of the better known proteoglycans are: aggrecan in cartilage, perlecan in basal laminae, decorin associated with fibroblasts in
collagen fibril assembly, and syndecan in embryonic tissues.

**Adhesive glycoproteins**

These proteins include molecules that mediate adhesion between cells and the extracellular matrix, often in association with collagens, proteoglycans or other matrix components. All of them are glycosylated and they are, therefore, glycoproteins. General connective tissue contains the well known families of fibronectins (and osteonectin in bone), laminins and tenascins; there is a rapidly growing list of other glycoproteins associated with extracellular adhesion (Pollard & Earnshaw 2007). They possess binding sites for other extracellular matrix molecules and for cell adhesion molecules (p. 5), especially the integrins; in this way they enable cells selectively to adhere to appropriate matrix structures (e.g. the basal lamina). They also function as signalling molecules, which are detected by cell surface receptors and initiate changes within the cytoplasm (e.g. to promote the formation of hemidesmosomes or other areas of strong adhesion; reorganize the cytoskeleton; promote or inhibit locomotion and cell division).

**Fibronectin**

Fibronectin is a large glycoprotein consisting of a dimer joined by disulphide links. Each subunit is composed of a string of large repetitive domains linked by flexible regions. Fibronectin subunits have binding sites for collagen, heparin and cell surface receptors, especially integrins, and so can promote adhesion between all these elements. In connective tissues, the molecules are able to bind to cell surfaces in an orderly fashion, to form short fibronectin filaments. The liver secretes a related protein, plasma fibronectin, into the circulation. The selective adhesion of different cell types to the matrix during development and in postnatal life is mediated by numerous isoforms of fibronectin generated by alternative splicing. Isoforms found in embryonic tissues are also expressed during wound repair, when they facilitate tissue proliferation and cell movements; the adult form is re-expressed once repair is complete.

**Laminin**

Laminin is a large (850 kDa) flexible molecule composed of three polypeptide chains (designated α, β, and γ). There are many isoforms of the different chains, and at least 18 types of laminin. The prototypical molecule has a cruciform shape, in which the terminal two-thirds are wound round each other to form the stem of a cross, and the shorter free ends form the upright and transverse members. Laminin bears binding sites for other extracellular matrix molecules such as heparan sulphate, type IV collagen and entactin and also for laminin receptor molecules (integrins) situated in cell plasma membranes. Laminin molecules can assemble themselves into flat regular meshworks, e.g. in the basal lamina.

**Tenascin**

Tenascin is large glycoprotein composed of six subunits that are joined at one end to form a structure that resembles the spokes of a wheel. There is a family of tenascin molecules, generated by alternative splicing of the tenascin gene transcript. Tenascin is abundant in embryonic tissues, but its distribution is restricted in the adult. It appears to be important in guiding cell migration and axonal growth in early development: it may either promote or inhibit these activities depending on the cell...
type and tenascin isoform.
CLASSIFICATION OF CONNECTIVE TISSUES

Connective and supporting tissues differ considerably in appearance, consistency and composition in different regions. These differences reflect local functional requirements and are related to the predominance of the cell types, the concentration, arrangement and types of fibre and the characteristics of the interfibrillar matrix. On these bases, general connective tissues can be classified into irregular and regular types, according to the degree of orientation of their fibrous components.

Irregular connective tissues

Irregular connective tissues can be further subdivided into loose, dense and adipose connective tissue.

Loose (areolar) connective tissue

Loose connective tissue is the most generalized form and is extensively distributed. Its chief function is to bind structures together, while still allowing a considerable amount of movement to take place. It constitutes the submucosa in the digestive tract and other viscera lined by mucosae, and the subcutaneous tissue in regions where this is devoid of fat (e.g. eyelids, penis, scrotum and labia), and it connects muscles, vessels and nerves with surrounding structures. It is present in the interior of organs, where it binds together the lobes and lobules of glands, forms the supporting layer (lamina propria) of mucosal epithelia and vascular endothelia, and lies within and between fascicles of muscle and nerve fibres.

Loose connective tissue consists of a meshwork of thin collagen and elastin fibres interlacing in all directions (see Fig. 2.12) to give a measure of both elasticity and tensile strength. The large meshes contain the soft, semi-fluid interfibrillar matrix or ground substance, and different connective tissue cells, which are scattered along the fibres or in the meshes. It also contains adipocytes, usually in small groups, and particularly around blood vessels.

A variant of loose connective tissue occurs in the choroid and the sclera of the eye, where large numbers of pigment cells (melanocytes) are also present.

Dense irregular connective tissue

Dense irregular connective tissue is found in regions that are under considerable mechanical stress and where protection is given to ensheathed organs. The matrix is relatively acellular and contains a high proportion of collagen fibres organized into thick bundles interweaving in three dimensions and imparting considerable strength. There are few active fibroblasts, which are usually flattened with heterochromatic nuclei. Dense irregular connective tissue occurs in: the reticular layer of the dermis; the superficial connective tissue sheaths of muscle and nerves and the adventitia of large blood vessels; the capsules of various glands and organs (e.g. testis, sclera of the eye, periosteum and perichondria).

Adipose tissue

A few adipocytes occur in loose connective tissue in most parts of the body. However, they constitute the principal component of adipose tissue (see Fig. 2.10), where they
are embedded in a vascular loose connective tissue, usually divided into lobules by stronger fibrous septa carrying the larger blood vessels. Adipose tissue only occurs in certain regions. In particular it is found in: subcutaneous tissue; the mesenteries and omenta; the female breast; bone marrow; as retro-orbital fat behind the eyeball; around the kidneys; deep to the plantar skin of the foot; as localized pads in the synovial membrane of many joints. Its distribution in subcutaneous tissue shows characteristic age and sex differences. Fat deposits serve as energy stores, sources of metabolic lipids, thermal insulation (subcutaneous fat) and mechanical shock-absorbers (e.g. soles of the feet, palms of the hands, gluteal region and synovial membranes).

**Regular connective tissues**

Regular connective tissues include highly fibrous tissues in which fibres are regularly orientated, either to form sheets such as fasciae and aponeuroses, or as thicker bundles such as ligaments or tendons (Fig. 2.14). The direction of the fibres within these structures is related to the stresses which they undergo, moreover, fibrous bundles display considerable interweaving, even within tendons, which increases their structural stability and resilience.
The fibroblasts that secrete the fibres may eventually become trapped within the fibrous structure, where they become compressed, relatively inactive cells with stellate profiles and small heterochromatic nuclei. These cells are called tendon cells. Fibroblasts on the external surface may be active in continued fibre formation and they constitute a pool of cells available for repair of injured tissue.

Although regular connective tissue is predominantly collagenous, some ligaments contain significant amounts of elastin, e.g. the ligamenta flava of the vertebral laminae and the vocal folds. The collagen fibres may form precise geometrical patterns, as in the cornea (p. 678).

**Mucoid tissue**

Mucoid tissue is a fetal or embryonic type of connective tissue, found chiefly as a stage in the development of connective tissue from mesenchyme. It exists in Wharton's jelly, which forms the bulk of the umbilical cord, and consists substantially of extracellular matrix, largely made up of hydrated mucoid material and a fine meshwork of collagen fibres, in which nucleated, fibroblast-like cells with branching process are found. Fibres are usually rare in typical mucoid tissue, although the full-term umbilical cord contains perivascular collagen fibres. Postnatally, mucoid tissue is seen in the pulp of a developing tooth, the vitreous body of the eye (a persistent form of mucoid tissue that contains few fibres or cells) and the nucleus pulposus of the intervertebral disc.
TRANSDIFFERENTIATION AND METAPLASIA

Transitions occur between populations of cells forming an epithelium (sheets of polarized cells) and mesenchymal types (where the cells lack polarity) during normal development (Section 3), but all well-described transitions between morphologically different cell types in postnatal life do not cross the epithelial–mesenchymal boundary. They are transitions between types of epithelial cell or, less frequently, between mesenchymal (connective tissue) cell types. Most instances of such transdifferentiation (metaplasia) are adaptive, to changing environmental conditions or trauma, and almost all are pathological; the altered cells are termed metaplastic. A very common and physiologically normal example is the squamous metaplasia of columnar secretory epithelium of the distal endocervical canal (Section 8), when exposed to the hormonally-stimulated vaginal environment. Gastric metaplasia of the lower oesophagus may occur when chronic reflux of gastric juices exposes its stratified squamous epithelial lining to acid, and the original epithelium is replaced by a mucus-secreting columnar epithelium typical of the stomach (Barrett’s oesophagus): this is pathological and susceptible to malignant change. Similarly, the respiratory epithelium (see Fig. 2.2D) of the upper airway often develops foci of stratified squamous metaplasia in response to irritants in cigarette smoke. Mesenchymal (osseous) metaplasia can occur, for example, in the fibrous connective tissue of muscles subjected to repeated damage, where trabeculi of bone develop. It is thought that stem cells (rather than the differentiated cells) in the affected tissue respond to changes in their environment by altering their differentiation pathway, a process which may be reversible if the stimulus is removed.
MUCOSA (MUCOUS MEMBRANE)

A mucosa or mucous membrane lines many internal hollow organs in which the inner surfaces are moistened by mucus, such as the intestines, conducting portions of the airway, and the genital and urinary tracts. The mucosa proper consists of an epithelial lining, which may have mucosal glands opening on to its surface, the underlying loose connective tissue, the lamina propria, and a thin layer of smooth muscle, the muscularis mucosae. This last layer is either absent from some mucosae, or is replaced by a layer of elastic fibres. The term mucous membrane reflects the fact that these tissues can all be peeled away as a sheet or membrane from underlying structures; the plane of separation occurs along the muscularis mucosae.

Submucosa is a layer of supporting connective tissue, which usually lies below the muscularis mucosae. It may contain mucous or seromucous submucosal glands, which convey their secretions through ducts to the mucosal surface. Most mucosae are also supported by one or more layers of smooth muscle, the muscularis externa. Contraction of this muscle may constrict the mucosal lumen (e.g. in the airway) or, where there are two or more muscle layers orientated in opposing directions (e.g. in the intestines), cause peristaltic movement of the viscus and the contents of its lumen. The outer surface of the muscle may be covered by a serosa or, where the structure is retroperitoneal or passes through the pelvic floor, by a connective tissue adventitia.

MUCUS

Mucus is a viscous suspension of complex glycoproteins (mucins) of various kinds, and is secreted by scattered individual epithelial (goblet) cells, a secretory surface epithelium (e.g. the stomach lining) or mucous and seromucous glands. The precise composition of the mucus varies with the tissue and secretory cells that produce it. All mucins consist of filamentous core proteins to which are attached carbohydrate chains, usually branched; salivary mucus contains nearly 600 chains. Carbohydrate residues include glucose, fucose, galactose and N-acetylgalactosamine (sialic acid). The terminals of some carbohydrate chains are identical with the blood group antigens of the ABO group in the majority of the population (secretors, bearing the secretor gene S<sup>e</sup>), and can be detected in salivary mucus by means of appropriate clinical tests. The long polymeric carbohydrate chains bind water and protect surfaces against drying; they also provide good lubricating properties. In concentrated form, mucins form viscous layers that protect the underlying tissues against damage.

Synthesis of mucus starts in the rough endoplasmic reticulum. It is then passed to the Golgi complex, where it is conjugated with sulphated
carbohydrates to form the glycoprotein, mucinogen, and this is exported in small, dense, membrane-bound vesicles, which swell as they approach the cell surface, with which they fuse before releasing their contents.
SEROSA (SEROUS MEMBRANE)

Serosa consists of a single layer of squamous mesothelial cells supported by an underlying layer of loose connective tissue that contains numerous blood and lymphatic vessels. Serosal cells are derived from embryonic mesenchyme and so share a common lineage with connective tissue cells. However, structurally they resemble squamous epithelia and they express keratin intermediate filaments. Serosa lines the pleural, pericardial and peritoneal cavities, covers the external surfaces of organs lying within those cavities and, in the abdomen, the mesenteries that envelop them. A potential space, filled with a small amount of protein-containing serous fluid – largely an exudate of interstitial fluid – exists between the outer parietal and the inner visceral layer of the serosa.
FASCIA

Fascia is a term applied to masses of connective tissue large enough to be visible to the unaided eye. Its structure is highly variable but, in general, collagen fibres in fascia tend to be interwoven and seldom show the compact, parallel orientation seen in tendons and aponeuroses.

Fascia that is organized into condensations on the surfaces of muscles – and their epimysial sheaths – and other tissues is termed investing fascia. Between muscles that move extensively, it takes the form of loose areolar connective tissue and provides a degree of mechanical isolation. It constitutes the loose packing of connective tissue around peripheral nerves, blood and lymph vessels as they pass between other structures and often links them together as neurovascular bundles. It forms a dense connective tissue layer investing some large vessels, e.g. the common carotid and femoral arteries, and its presence here may be functionally significant, aiding venous return by approximating large veins to pulsating arteries.

SUPERFICIAL FASCIA

Superficial fascia is a layer of loose connective tissue of variable thickness that merges with the deep aspect of the dermis; it is thus also known as the hypodermis. It is often adipose, particularly between muscle and skin. It allows increased mobility of skin, and the adipose component contributes to thermal insulation and constitutes a store of energy for metabolic use. Subcutaneous nerves, vessels and lymphatics travel in the superficial fascia; their main trunks lie in its deepest layer, where adipose tissue is sparse. In the head and neck, superficial fascia also contains a group of striated muscles – collectively termed the muscles of facial expression (Ch. 29) – which are a remnant of more extensive sheets of skin-associated musculature found in other mammals (panniculus carnosus).

The quantity and distribution of subcutaneous fat differs in the sexes. It is generally more abundant and widely distributed in females. In males, it diminishes from the trunk to the extremities; this distribution becomes more obvious in middle age, when the total amount increases in both sexes. There is an association with climate (rather than race), and superficial fat is more abundant in colder geographical regions. Superficial fascia is most distinct on the lower anterior abdominal wall, where it contains much elastic tissue and appears many-layered as it passes through the inguinal regions into the thighs. It is well differentiated in the limbs and the perineum, but is thin where it passes over the dorsal aspects of the hands and feet, the sides of the neck and face, around the anus and over the penis and scrotum, and is almost absent from the external ears. Typical superficial fascia is lacking in the palms and soles, where numerous strong connective tissue collagenous bands tether the dermis of the skin to underlying structures. Also atypical is
the skin of the scalp, where dense dermal connective tissue and the epicranial aponeurosis are bound together as a layer that ‘rides’ on loose connective tissue overlying the periosteum of the skull.
DEEP FASCIA

Deep fascia is also composed mainly of collagenous fibres, but these are compacted and in many cases arranged so regularly that the deep fascia may be indistinguishable from aponeurotic tissue. In limbs, where deep fascia is well developed, the collagen fibres are longitudinal or transverse, and condense into tough, inelastic sheaths around the musculature.

CHAPTER 3 – Nervous system

The nervous system has two major divisions, the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS consists of the brain and spinal cord and contains the majority of neuronal cell bodies. The PNS includes all nervous tissue outside the central nervous system and is subdivided into the cranial and spinal nerves, peripheral autonomic nervous system (ANS) (including the enteric nervous system of the gut wall, ENS) and special senses (taste, olfaction, vision, hearing and balance). It is composed mainly of the axons of sensory and motor neurones that pass between the CNS and the body. However, the ENS contains as many intrinsic neurones in its ganglia as the entire spinal cord, is not connected directly to the CNS, and may be considered separately as a third division of the nervous system (Gershon 1998).

The CNS is derived from the neural tube (Ch. 24). The cell bodies of neurones are often grouped together in discrete areas termed nuclei, or they may form more extensive layers or masses of cells; collectively they constitute grey matter. Neuronal dendrites and synaptic contacts are mostly confined to areas of grey matter, and they form part of its meshwork of neuronal and glial processes termed the neuropil. Their axons join bundles of nerve fibres that tend to be grouped separately to form tracts. In the spinal cord, cerebellum, cerebral cortices (Chs 20, 22) and some other areas, concentrations of tracts constitute the white matter, so called because the axons are often ensheathed in lipid-rich sheaths of myelin which is white when fresh (Fig. 3.1).

The PNS is composed of the efferent axons (fibres) of motor neurones situated inside the CNS, and the cell bodies of sensory neurones (grouped together as ganglia) and their afferent processes. Sensory cells in dorsal root ganglia give off both centrally and peripherally directed processes: there are no synapses on their cell bodies. Also included are ganglionic neurones of the ANS, which receive synaptic contacts from the peripheral fibres of preganglionic autonomic neurones whose cell bodies lie within the CNS. Neuronal cell bodies in peripheral ganglia are all derived embryologically from cells which migrate from the neural crest (p. 201).

When the neural tube is formed during prenatal development its walls thicken greatly but do not completely obliterate the cavity within. The latter remains in the spinal cord as the narrow central canal, and in the brain it becomes greatly expanded to form a series of interconnected cavities called the ventricular system. In the fore- and hindbrains, parts of the neural tube roof do not generate nerve cells but become thin folded sheets of secretory tissue which are invaded by blood vessels and are called the choroid plexuses. The plexuses secrete cerebrospinal fluid (CSF) which fills the ventricles and subarachnoid spaces and penetrates the intercellular spaces of the brain and spinal cord to create their interstitial fluid. The CNS has a rich blood supply, which is essential to sustain its high metabolic rate. The blood–brain barrier places considerable restrictions on the substances which can diffuse from the bloodstream into the nervous tissue.

Neurones encode information, conduct it over considerable distances, and then transmit it to other neurones or to various non-neural cells. The movement of this information within the nervous system depends on the rapid conduction of transient electrical impulses along neuronal plasma membranes. Transmission to other cells is mediated by secretion of neurotransmitters at special junctions either with other
neurones (synapses), or with cells outside the nervous system, e.g. muscle cells (neuromuscular junctions), gland cells, adipose tissue, etc. and this causes changes in their behaviour.

The nervous system contains large populations of non-neuronal cells, neuroglia or glia, which, whilst not electrically active in the same way, are responsible for creating and maintaining an appropriate environment in which neurones can operate efficiently. Indeed, it is now known that two-way communication between neurones and glial cells is essential for normal neural activity (reviewed in Fields & Stevens-Graham 2002). In the CNS, glia outnumber neurones by 10–50 times and consist of microglia and macroglia. Macroglia are further subdivided into three main types, oligodendrocytes, astrocytes and ependymal cells. The principal glial cell of the PNS is the Schwann cell. Satellite cells surround each neuronal soma in ganglia.

Fig. 3.1 Section through the human cerebellum stained to show the arrangement in the brain of the central white matter (WM, deep pink), and the highly folded outer grey matter (GM). In the cerebellum, GM consists of an inner granular layer of tightly packed small neurones (blue) and an outermost molecular layer (pale pink) where neuronal processes make
Most of the neurones in the CNS are either clustered into nuclei, columns or layers, or dispersed within grey matter. Neurones of the PNS are confined to ganglia. Irrespective of location, neurones share many general features, which are discussed here in the context of central neurones. Special characteristics of ganglionic neurones and their adjacent tissues are discussed on page 55–6.

Neurones exhibit great variability in their size (cell bodies range from 5 to 100 µm diameter) and shapes. Their surface areas are extensive because most neurones display numerous narrow branched cell processes. They usually have a rounded or polygonal cell body (perikaryon or soma). This is a central mass of cytoplasm which encloses a nucleus and gives off long, branched extensions, with which most intercellular contacts are made. Typically, one of these processes, the axon, is much longer than the others, the dendrites (Fig. 3.2). Dendrites conduct electrical signals towards a soma whereas axons conduct impulses away from it.
Neurones can be classified according to the number and arrangement of their processes. Multipolar neurones (Fig. 3.3) are common: they have an extensive dendritic tree which arises from either a single primary dendrite or directly from the soma, and a single axon. Bipolar neurones, which typify neurones of the special sensory systems, e.g. the retina (p. 697), have only a single dendrite which emerges from the soma opposite the axonal pole. Unipolar neurones which transmit general sensation, e.g. dorsal root ganglion neurones, have a single short process which bifurcates into peripheral and central processes (p. 55). This arrangement arises by the fusion of the proximal axonal and dendritic processes of a bipolar neurone during development: they may also, therefore, be termed pseudounipolar. Neurones are also classified according to whether their axons terminate locally on other neurones.
(interneurones), or transmit impulses over long distances, often to distinct territories via defined tracts (projection neurones).

**Fig. 3.3** The variety of shapes of neurones and their processes. The inset shows a human multipolar retinal ganglion cell, filled with fluorescent dye by microinjection.

*(Inset by courtesy of Drs Richard Wingate, James Morgan and Ian Thompson, King’s College, London.)*

Neurones are postmitotic cells and, with few exceptions, they are not replaced when lost.

**SOMA**

The plasma membrane of the soma is unmyelinated and contacted by inhibitory and excitatory axosomatic synapses: very occasionally, somasomatic and dendrosomatic contacts may be made. The non-synaptic surface is covered by either astrocytic or satellite oligodendrocyte processes.

The cytoplasm of a typical soma (Fig. 3.2) is rich in rough and smooth endoplasmic
reticulum and free polyribosomes, indicating a high level of protein synthetic activity. Free polyribosomes often congregate in large groups associated with the rough endoplasmic reticulum. These aggregates of RNA-rich structures are visible by light microscopy as basophilic Nissl bodies or granules. They are more obvious in large, highly active cells, such as spinal motor neurones (Fig. 3.4), which contain large stacks of rough endoplasmic reticulum and polyribosome aggregates. Maintenance and turnover of cytoplasmic and membranous components are necessary in all cells: the huge total volume of cytoplasm within the soma and processes of many neurones requires a considerable commitment of protein synthetic machinery. Neurones also synthesize other proteins (enzyme systems, etc.) involved in the production of neurotransmitters and in the reception and transduction of incoming stimuli. Various transmembrane channel proteins and enzymes are located at the surfaces of neurones where they are associated with movements of ions. The apparatus for protein synthesis (including RNA and ribosomes) occupies the soma and dendrites, but is usually absent from axons.
The nucleus is characteristically large, round and euchromatic and contains at least one prominent nucleolus; these are features typical of all cells engaged in substantial levels of protein synthesis. The cytoplasm contains many mitochondria and moderate numbers of lysosomes. Golgi complexes are usually close to the nucleus, near the bases of the main dendrites and opposite the axon hillock.

The neuronal cytoskeleton is a prominent feature of its cytoplasm and gives shape, strength and support to the dendrites and axons. A number of neurodegenerative diseases are characterized by abnormal aggregates of cytoskeletal proteins (reviewed in Cairns et al 2004). Neurofilaments (the intermediate filaments of neurones) and microtubules are abundant in the soma and along dendrites and axons: the proportions vary with the type of neurone and cell process. Bundles of neurofilaments constitute neurofibrils which can be seen by light microscopy in silver stained or immunolabelled sections. Neurofilaments are heteropolymers of proteins assembled from three polypeptide subunits, NF-L (68 kilodaltons [kDa]), NF-M (160 kDa) and NF-H (200 kDa). NF-M and NF-H have long C-terminal domains which project as side arms from the assembled neurofilament and bind to neighbouring filaments. They can be heavily phosphorylated, particularly in the highly stable neurofilaments of mature axons, and are thought to give axons their tensile strength. Some axons are almost filled by neurofilaments.

Microtubules are important in axonal transport, although dendrites usually have more microtubules than axons. Centrioles persist in mature postmitotic neurones, where they are concerned with the generation of microtubules rather than cell division. Centrioles are associated with cilia on the surfaces of developing neuroblasts. Their significance, other than at some sensory endings (e.g. the olfactory mucosa, p. 553), is not known.

Pigment granules (Fig. 3.5) appear in certain regions, e.g. neurones of the substantia nigra contain neuromelanin, probably a waste product of catecholamine synthesis. In the locus coeruleus a similar pigment, rich in copper, gives a bluish colour to the neurones. Some neurones are unusually rich in certain metals which may form a component of enzyme systems, e.g. zinc in the hippocampus and iron in the oculomotor nucleus. Ageing neurones, especially in spinal ganglia, accumulate granules of lipofuscin (senility pigment) in residual bodies, which are lysosomes packed with partially degraded lipoprotein material (corpora amylaceae).
Fig. 3.5 Neurones in the substantia nigra of the human midbrain, showing cytoplasmic granules of neuromelanin pigment.
DENDRITES

Dendrites are highly branched, usually short processes which project from the soma (Fig. 3.2). The branching patterns of many dendritic arrays are probably established by random adhesive interactions between dendritic growth cones and afferent axons that occur during development. There is an overproduction of dendrites in early development, and this is pruned in response to functional demand as the nervous system matures and information is processed through the dendritic tree. There is evidence that dendritic trees may be plastic structures throughout adult life, expanding and contracting as the traffic of synaptic activity varies through afferent axodendritic contacts (for review see Wong & Ghosh 2002). Groups of neurones with similar functions have a similar stereotypic tree structure (Fig. 3.6), suggesting that the branching patterns of dendrites are important determinants of the integration of the afferent inputs that converge on the tree.

Fig. 3.6 Purkinje neurone from the cerebellum of a rat stained by the Golgi–Cox method, showing the extensive two-
Dendrites differ from axons in many respects. They represent the afferent rather than the efferent system of the neurone, and receive both excitatory and inhibitory axodendritic contacts. They may also make dendrodendritic and dendrosomatic connections (see Fig. 3.9), some of which are reciprocal. Synapses occur either on small projections called dendritic spines or on the smooth dendritic surface. Dendrites contain ribosomes, smooth endoplasmic reticulum, microtubules, neurofilaments, actin filaments and Golgi complexes. Their neurofilament proteins are poorly phosphorylated and their microtubules express the microtubule-associated protein (MAP)-2 almost exclusively in comparison with axons.

The shapes of dendritic spines range from simple protrusions to structures with a slender stalk and expanded distal end. Most spines are not more than 2 µm long, and have one or more terminal expansions; they can also be short and stubby, branched or bulbous. Free ribosomes and polyribosomes are concentrated at the base of the spine. Ribosomal accumulations near synaptic sites provide a mechanism for activity-dependent synaptic plasticity through the local regulation of protein synthesis.
**AXONS**

The axon originates either from the soma or from the proximal segment of a dendrite, at a specialized region free of Nissl granules, the axon hillock (Fig. 3.2). Action potentials are initiated here. The axonal plasma membrane (axolemma) is undercoated at the hillock by a concentration of cytoskeletal molecules, including spectrin and actin fibrils, which are important in anchoring numerous voltage-sensitive channels to the membrane. The axon hillock is unmyelinated and often participates in inhibitory axo-axonal synapses. It is unique because it contains ribosomal aggregates immediately below the postsynaptic membrane.

In the CNS, small, unmyelinated axons lie free in the neuropil, whereas in the PNS they are embedded in Schwann cell cytoplasm. Myelin, which is formed around almost all axons >2 µm diameter by oligodendrocytes in the CNS and Schwann cells in the PNS, begins at the distal end of the axon hillock. Nodes of Ranvier are specialized constricted regions of myelin-free axolemma where action potentials are generated and where an axon may branch. In both CNS and PNS, the territory of a myelinated axon between adjacent nodes is called an internode: the region close to a node, where the myelin sheath terminates, is called the paranode. Myelin thickness and internodal lengths are, in general, positively correlated with axon diameter. The density of sodium channels in the axolemma is highest at nodes of Ranvier, and very low along internodal membranes: sodium channels are spread more evenly within the axolemma of unmyelinated axons. Fast potassium channels are present in the paranodal regions of myelinated axons. Fine processes of glial cytoplasm (astrocytic in the CNS, Schwann cell in the PNS) surround the nodal axolemma.

The terminals of an axon are unmyelinated and most expand into presynaptic boutons which may form connections with axons, dendrites, neuronal somata or, in the periphery, muscle fibres, glands and lymphoid tissue. Exceptions include the free afferent sensory endings in e.g. the epidermis, which are unspecialized structurally, and the peripheral terminals of afferent sensory fibres with encapsulated endings (see Fig. 3.30). Axon terminals may themselves be contacted by other axons, forming axoaxonal presynaptic inhibitory circuits. Further details of neuronal microcircuitry are given in Kandel et al (2000).
Axons contain microtubules, neurofilaments, mitochondria, membrane vesicles, cisternae, and lysosomes. Axons do not usually contain ribosomes or Golgi complexes, except at the axon hillock: exceptionally, the neurosecretory fibres of hypothalamo-hypophysial neurones contain the mRNA of neuropeptides. Organelles are differentially distributed along axons, e.g. there is a greater density of mitochondria and membrane vesicles in the axon hillock, at nodes, and in presynaptic endings. Axonal microtubules are interconnected by cross-linking MAPs, of which tau is the most abundant. Microtubules have an intrinsic polarity, and in axons all microtubules are uniformly orientated with their rapidly growing ends directed away from the soma towards the axon terminal. Neurofilament proteins ranging from high to low molecular weights are highly phosphorylated in mature axons, whereas growing and regenerating axons express a calmodulin-binding membrane-associated phosphoprotein, growth-associated protein-43 (GAP-43), as well as poorly phosphorylated neurofilaments.

Neurones respond differently to injury depending on whether the damage occurs in the CNS or the PNS. The glial microenvironment of a damaged central axon does not facilitate axonal regrowth, consequently reconnection with original synaptic targets does not normally occur. In marked contrast, the glial microenvironment in the PNS is capable of facilitating axonal regrowth. However, functional outcome of clinical repair of a large mixed peripheral nerve, especially if the injury occurs some distance from the target organ, or produces a long defect in the damaged nerve, is frequently unsatisfactory.

Axoplasmic flow
Neuronal organelles and cytoplasm are in continual motion. Bidirectional streaming of vesicles along axons results in a net transport of materials from the soma to the terminals, with more limited movement in the opposite direction. Two major types of transport occur, one slow, and one relatively fast. Slow axonal transport is a bulk flow of axoplasm only in the anterograde direction, carrying cytoskeletal proteins and soluble, non-membrane bound proteins from the soma to the terminals at a rate of approximately 0.1–3 mm a day. In contrast, fast axonal transport carries membrane-bound vesicular material (endosomes and lysosomal autophagic vacuoles) and mitochondria at approximately 200 mm a day in the retrograde direction (towards the soma) and approximately 40 mm per day anterogradely (in particular, synaptic vesicles containing neurotransmitters).

Rapid flow depends on microtubules. Vesicles with side projections line up along microtubules and are transported along them by their side-arms. Two microtubule-based motor proteins with ATPase activity are involved in fast transport: kinesin family proteins are responsible for the fast component of anterograde transport, and cytoplasmic dynein is responsible for retrograde transport. Microtubule-dependent axonal transport is reviewed in Guzik and Goldstein (2004). Retrograde transport mediates the movement of neurotrophic viruses, e.g. herpes zoster, rabies and polio, from peripheral terminals, and their subsequent concentration in the neuronal soma.
SYNAPSES

Transmission of impulses across specialized junctions (synapses) between two neurones is largely chemical and depends on the release of neurotransmitters from the presynaptic side. This causes a change in the electrical state of the postsynaptic neuronal membrane, resulting in either its depolarization or hyperpolarization.

The patterns of axonal termination vary considerably. A single axon may synapse with one neurone (e.g. climbing fibres ending on cerebellar Purkinje neurones), or more often with many neurones (e.g. cerebellar parallel fibres, which provide an extreme example of this phenomenon (p. 302). In synaptic glomeruli, e.g. in the olfactory bulb and cerebellum, and synaptic cartridges, groups of synapses between two or many neurones form interactive units encapsulated by neuroglia (Fig. 3.7).
Electrical synapses (direct communication via gap junctions) are rare in the human CNS and are confined largely to groups of neurones with tightly coupled activity, e.g. the inspiratory centre in the medulla. They will not be discussed further here.

**Classification of chemical synapses**

Chemical synapses have an asymmetric structural organization (Fig. 3.8 and Fig. 3.9) in keeping with the unidirectional nature of their transmission. Typical chemical synapses share a number of important features. They all display an area of presynaptic membrane apposed to a corresponding postsynaptic membrane: the two are separated by a narrow (20–30 nm) gap, the synaptic cleft. Synaptic vesicles containing neurotransmitter lie on the presynaptic side, clustered near a dense plaque on the cytoplasmic aspect of the presynaptic membrane. A corresponding region of submembrane density is present on the postsynaptic side. Together these define the active zone, the area of the synapse where neurotransmission takes place.
Chemical synapses can be classified according to a number of different parameters including the neuronal regions forming the synapse, their ultrastructural characteristics, the chemical nature of their neurotransmitter(s) and their effects on the electrical state of the postsynaptic neurone. The following classification is limited to associations between neurones. Neuromuscular junctions share many (though not all) of these parameters, and are often referred to as peripheral synapses. They are described separately on page 63.

Synapses can occur between almost any surface regions of the participating neurones. The most common type occurs between an axon and either a dendrite or a soma, when the axon is expanded as a small bulb or bouton (Fig. 3.8, Fig. 3.9). This may be a terminal of an axonal branch (terminal bouton) or one of a row of bead-like endings, when the axon makes contact at several points, often with more than one neurone (bouton de passage). Boutons may synapse with dendrites, including dendritic spines or the flat surface of a dendritic shaft, a soma (usually on its flat surface, but occasionally on spines), the axon hillock and the terminal boutons of other axons.

The connection is classified according to the direction of transmission, and the incoming terminal region is named first. Most common are axodendritic synapses, although axosomatic connections are frequent. All other possible combinations are found but are less common, i.e. axoaxonic, dendroaxonic, dendrodendritic, somatodendritic or somatosomatic. Axodendritic and axosomatic synapses occur in all regions of the CNS and in autonomic ganglia, including those of the ENS. The other types appear restricted to regions of complex interaction between larger sensory neurones and microneurones, e.g. in the thalamus.

Ultrastructurally, synaptic vesicles may be internally clear or dense, and of different size (loosely categorized as small or large) and shape (round, flat or pleomorphic, i.e. irregularly shaped). The submembranous densities may be thicker on the postsynaptic than on the presynaptic side (asymmetric synapses), or equivalent in thickness (symmetrical synapses). Synaptic ribbons are found at sites of neurotransmission in the retina and inner ear. They have a distinctive morphology, in that the synaptic vesicles are grouped around a ribbon- or rod-like density orientated perpendicular to the cell membrane (Fig. 3.9).
Synaptic boutons make obvious close contacts with postsynaptic structures, but many other terminals lack specialized contact zones. Areas of transmitter release occur in the varicosities of unmyelinated axons, where effects are sometimes diffuse, e.g. the aminergic pathways of the basal ganglia and in autonomic fibres in the periphery. In some instances, such axons may ramify widely throughout extensive areas of the brain and affect the behaviour of very large populations of neurones, e.g. the diffuse cholinergic innervation of the cerebral cortices. Pathological degeneration of these pathways can therefore cause widespread disturbances in neural function.

Neurones express a variety of neurotransmitters, either as one class of neurotransmitter per cell or more often as several. Good correlations exist between some types of transmitter and specialized structural features of synapses. In general, asymmetric synapses with relatively small spherical vesicles are associated with acetylcholine (ACh), glutamate, serotonin (5-hydroxytryptamine, 5-HT), and some amines; those with dense-core vesicles include many peptidergic synapses and other amines (e.g. noradrenaline (norepinephrine), adrenaline (epinephrine), dopamine). Symmetrical synapses with flattened or pleomorphic vesicles have been shown to contain either γ-aminobutyric acid (GABA) or glycine.

Neurosecretory endings found in various parts of the brain and in neuroendocrine glands and cells of the dispersed neuroendocrine system (see below; p. 31) share many features with presynaptic boutons. They all contain peptides or glycoproteins within dense-core vesicles. The latter are of characteristic size and appearance: they are often ellipsoidal or irregular in shape, and relatively large, e.g. oxytocin and vasopressin vesicles in the neurohypophysis may be up to 200 nm across.

Synapses may cause depolarization or hyperpolarization of the postsynaptic membrane, depending on the neurotransmitter released and the classes of receptor molecule in the postsynaptic membrane. Depolarization of the postsynaptic membrane results in excitation of the postsynaptic neurone, whereas hyperpolarization has the effect of transiently inhibiting electrical activity. Subtle variations in these responses may also occur at synapses where mixtures of neuromediators are present and their effects are integrated.

Type I and II synapses

There are two broad categories of synapse: type I synapses, in which the cytoplasmic density is thicker on the postsynaptic side, and type II synapses, in which the pre- and post-synaptic densities are more symmetrical but thinner. Type I boutons contain a predominance of small spherical vesicles approximately 50 nm in diameter, and type II boutons contain a variety of flat forms. Throughout the CNS, type I synapses are generally excitatory and type II, inhibitory. In a few instances types I and II synapses are found in close proximity, orientated in opposite directions across the synaptic cleft (a reciprocal synapse).

Mechanisms of synaptic activity

Synaptic activation begins with arrival of one or more action potentials at the presynaptic bouton, which causes the opening of voltage-sensitive calcium channels in the presynaptic membrane. The response time in typical fast-acting synapses is
then very rapid; classic neurotransmitter (e.g. ACh) is released in less than a millisecond, which is faster than the activation time of a classic second messenger system on the presynaptic side. The influx of calcium activates Ca\(^{2+}\)-dependent protein kinases. This uncouples synaptic vesicles from a spectrin-actin meshwork within the presynaptic ending, to which they are bound via synapsins I and II. The vesicles dock with the presynaptic membrane, through processes not yet fully understood, and their membranes fuse to open a pore through which neurotransmitter diffuses into the synaptic cleft.

Once the vesicle has discharged its contents, its membrane is incorporated into the presynaptic plasma membrane and is then more slowly recycled back into the bouton by endocytosis around the edges of the active site. The time between endocytosis and re-release may be approximately 30 seconds; newly recycled vesicles compete randomly with previously stored vesicles for the next cycle of neurotransmitter release. The fusion of vesicles with the presynaptic membrane is responsible for the observed quantal behaviour of neurotransmitter release, both during neural activation and spontaneously, in the slightly leaky resting condition.

Postsynaptic events vary greatly, depending on the receptor molecules and their related molecular complexes. Receptors are generally classed as either ionotropic or metabotropic. Ionotropic receptors function as ion channels, so that conformational changes induced in the receptor protein when it binds the neurotransmitter cause the opening of an ion channel within the same protein assembly, thus causing a voltage change within the postsynaptic cell. Examples are the nicotinic ACh receptor and the N-methyl-D-aspartate (NMDA) glutamate receptor. Alternatively, the receptor and ion channel may be separate molecules, coupled by G-proteins, some via a complex cascade of chemical interactions (a second messenger system), e.g. the adenylate cyclase pathway. Postsynaptic effects are generally rapid and short-lived, because the transmitter is quickly inactivated either by an extracellular enzyme (e.g. acetylcholinesterase, AChE), or by uptake by neuroglial cells. Examples of such metabotropic receptors are the muscarinic Ach receptor and 5-HT receptor.

**Neurohormones**

Neurohormones are included in the class of molecules with neurotransmitter-like activity. They are synthesized in neurones and released into the blood circulation by exocytosis at synaptic terminal-like structures. As with classic endocrine gland hormones, they may act at great distances from their site of secretion. Neurons secrete into the CSF or local interstitial fluid to affect other cells, either diffusely or at a distance. To encompass this wide range of phenomena the general term neuromediation has been used, and the chemicals involved are called neuromediators.

**Neuromodulators**

Some neuromediators do not appear to affect the postsynaptic membrane directly, but they can affect its responses to other neuromediators, either enhancing their activity (by increasing or prolonging the immediate response), or perhaps limiting or inhibiting their action. These substances are called neuromodulators. A single synaptic terminal may contain one or more neuromodulators in addition to a
neurotransmitter, usually (though not always) in separate vesicles. Neuropeptides (see below) are nearly all neuromodulators, at least in some of their actions. They are stored within dense granular synaptic vesicles of various sizes and appearances.

**Development and plasticity of synapses**

Embryonic synapses first appear as inconspicuous dense zones flanking synaptic clefts. Immature synapses often appear after birth, suggesting that they may be labile, and are reinforced if transmission is functionally effective, or withdrawn if redundant. This is implicit in some theories of memory, which postulate that synapses are modifiable by frequency of use, to establish preferential conduction pathways. Evidence from hippocampal neurones suggests that even brief synaptic activity can increase the strength and sensitivity of the synapse for some hours or longer (long-term potentiation, LTP). During early postnatal life, the normal developmental increase in numbers and sizes of synapses and dendritic spines depends on the degree of neural activity and is impaired in areas of damage or functional deprivation.

**Neurotransmitter molecules**

Until recently the molecules known to be involved in chemical synapses were limited to a fairly small group of classic neurotransmitters, e.g. ACh, noradrenaline, adrenaline, dopamine and histamine, all of which had well-defined rapid effects on other neurones, muscle cells or glands. However, many synaptic interactions cannot be explained on the basis of classic neurotransmitters, and it is now known that other substances, particularly some amino acids such as glutamate, glycine, aspartate, GABA and the monoamine, serotonin, also function as transmitters. Substances first identified as hypophysial hormones or as part of the dispersed neuroendocrine system (see below) of the alimentary tract, can be detected widely throughout the CNS and PNS, often associated with functionally integrated systems. Many of these are peptides: more than 50 (together with other candidates), function mainly as neuromodulators and influence the activities of classic transmitters.

**Acetylcholine**

Acetylcholine (ACh) is perhaps the most extensively studied neurotransmitter of the classic type. Its precursor, choline, is synthesized in the neuronal soma and transported to the axon terminals where it is acetylated by the enzyme choline acetyl transferase (ChAT), and stored in clear spherical vesicles approximately 50 nm in diameter. ACh is synthesized by motor neurones and released at all their motor terminals on skeletal muscle. It is released by preganglionic fibres at synapses in parasympathetic and sympathetic ganglia, and many parasympathetic, and some sympathetic, ganglionic neurones are cholinergic. In some sites e.g. at neuromuscular junctions, ACh is also associated with the degradative extracellular enzyme AChE.

The effects of ACh on nicotinic receptors (i.e. those in which nicotine is an agonist) are rapid and excitationary. In the peripheral autonomic nervous system, the slower, more sustained excitationary effects of cholinergic autonomic endings are mediated by muscarinic receptors via a second messenger system.
Monoamines

Monoamines include the catecholamines (noradrenaline, adrenaline and dopamine), and the indoleamine serotonin (5-hydroxytryptamine, 5-HT) and histamine. They are synthesized by neurones in sympathetic ganglia and by their homologues, the chromaffin cells of the suprarenal medulla and paraganglia. Within the CNS, the somata of monoaminergic neurones lie mainly in the brainstem, although their axons ramify widely into all parts of the nervous system. Monoaminergic cells are also present in the retina.

Noradrenaline is the chief transmitter present in sympathetic ganglionic neurones with endings in various tissues, notably smooth muscle and glands, and in other sites including adipose and haemopoietic tissues, and the corneal epithelium. It is also found at widely distributed synaptic endings within the CNS, many of them terminals of neuronal somata situated in the locus coeruleus in the medullary floor. The actions of noradrenaline depend on its site of action, and vary with the type of postsynaptic receptor. In some cases, e.g. the neurones of the submucosal plexus of the intestine and of the locus coeruleus, it is strongly inhibitory via actions on the α2-adrenergic receptor, whereas the β-receptors, e.g. of vascular smooth muscle, mediate depolarization and therefore vasoconstriction. Adrenaline is present in central and peripheral nervous pathways and occurs with noradrenaline in the suprarenal medulla. Both adrenaline and noradrenaline are found in dense-cored synaptic vesicles approximately 50 nm diameter.

Dopamine is a neuromediator of considerable clinical importance, found mainly in neurones with cell bodies in the telencephalon, diencephalon and mesencephalon. A major dopaminergic neuronal population in the midbrain constitutes the substantia nigra, so called because its cells contain neuromelanin, a black granular byproduct of dopamine synthesis. Dopaminergic endings are particularly numerous in the corpus striatum, limbic system and cerebral cortex. Structurally, dopaminergic synapses contain numerous dense-cored vesicles that resemble those containing noradrenaline. Pathological reduction in dopaminergic activity has widespread effects on motor control, affective behaviour and other neural activities, as seen in Parkinson's syndrome (Ch. 22).

Serotonin and histamine are found in neurones mainly within the CNS. Serotonin is typically synthesized in small midline neuronal clusters in the brainstem, mainly in the raphe nuclei: the axons from these neurones ramify extensively throughout the entire brain and spinal cord. Synaptic terminals contain rounded, clear vesicles approximately 50 nm diameter and are of the asymmetrical type. Histaminergic neurones appear to be relatively sparse, and are restricted largely to the hypothalamus.

Amino acids

GABA is a major inhibitory transmitter released at the terminals of local circuit neurones within the brainstem and spinal cord (e.g. the recurrent inhibitory Renshaw loop), cerebellum (where it is the main transmitter of Purkinje cells), basal ganglia, cerebral cortex, thalamus and subthalamus. It is stored in flattened or pleomorphic
vesicles within symmetrical synapses. GABA may be inhibitory to the postsynaptic neurone, or may mediate either presynaptic inhibition or facilitation, depending on the synaptic arrangement.

Glutamate and aspartate are major excitatory transmitters present widely within the CNS, including the major projection pathways from the cortex to the thalamus, tectum, substantia nigra and pontine nuclei. They are found in the central terminals of the auditory and trigeminal nerves, and glutamate is present in the terminals of parallel fibres ending on Purkinje cells in the cerebellum. Structurally, glutamate and aspartate are associated with asymmetrical synapses containing small (approximately 30 nm) round, clear synaptic vesicles.

Glycine is a well-established inhibitory transmitter of the CNS, particularly the lower brainstem and spinal cord, where it is mainly found in local circuit neurones.

Nitric oxide

Nitric oxide (NO) is of considerable importance at autonomic and enteric synapses, where it mediates smooth muscle relaxation. NO has been implicated in the mechanism of long-term potentiation. It is able to diffuse freely through cell membranes, and so is not under such tight quantal control as vesicle-mediated neurotransmission.

Neuropeptides

Many neuropeptides coexist with other neuromediators in the same synaptic terminals. As many as three peptides often share a particular ending with a well-established neurotransmitter, in some cases within the same synaptic vesicles. Some peptides occur both in the CNS and PNS, particularly in the ganglion cells and peripheral terminals of the ANS, whilst others are entirely restricted to the CNS. Only a few examples are given here.

Most of the neuropeptides are classified according to the site where they were first discovered. For example, the gastrointestinal peptides were initially found in the gut wall, and a group that includes releasing hormones, adenohypophysial and neurohypophysial hormones was first associated with the pituitary gland. Some of these peptides are closely related to each other in their chemistry, because they are derived from the same gene products (e.g. the pro-opiomelanocortin group), which are cleaved to produce smaller peptides.

Substance P (SP) was the first of the peptides to be characterized as a gastrointestinal neuromediator and is considered to be the prototypic neuropeptide. It is an 11-amino acid polypeptide that belongs to the tachykinin neuropeptide family, and is a major neuromediator in the brain and spinal cord. Contained within large granular synaptic vesicles, SP is found in approximately 20% of dorsal root and trigeminal ganglion cells, in particular in small nociceptive neurones, and in some fibres of the facial, glossopharyngeal and vagal nerves. Within the CNS, SP is present in several apparently unrelated major pathways, and has been described in the limbic system, basal ganglia, amygdala and hypothalamus. Its known action is prolonged postsynaptic excitation, particularly from nociceptive afferent terminals, which sustains the effects of noxious stimuli. SP is one of the main neuropeptides
that trigger an inflammatory response in the skin and has also been implicated in the vomiting reflex, changes in cardiovascular tone, stimulation of salivary secretion, smooth muscle contraction, and vasodilation.

Vasoactive intestinal polypeptide (VIP), another gastrointestinal peptide, is widely present in the CNS, where it is probably an excitatory neurotransmitter or neuromodulator. It is found in distinctive bipolar neurones of the cerebral cortex; small dorsal root ganglion cells, particularly of the sacral region; the median eminence of the hypothalamus, where it may be involved in endocrine regulation; intramural ganglion cells of the gut wall; sympathetic ganglia.

Somatostatin (ST, somatotropin release inhibiting factor) has a broad distribution within the central nervous system, and may be a central neurotransmitter or neuromodulator. It also occurs in small dorsal root ganglion cells. β-Endorphin, leu- and metenkephalins and the dynorphins belong to a group of peptides called the naturally occurring opiates that possess analgesic properties. They bind to opiate receptors in the brain where, in general, their action seems to be inhibitory. Enkephalins have been localized in many areas of the brain. Their particular localization in the septal nuclei, amygdaloid complex, basal ganglia and hypothalamus, suggests that they are important mediators in the limbic system and in the control of endocrine function. They have also been implicated strongly in the central control of pain pathways, because they are found in the periaqueductal grey matter of the midbrain, a number of reticular raphe nuclei, the spinal nucleus of the trigeminal nerve and the substantia gelatinosa of the spinal cord. The enkephalinergic pathways exert an important presynaptic inhibitory action on nociceptive afferents in the spinal cord and brainstem. Like many other neuromediators, enkephalins also occur widely in other parts of the brain in lower concentrations.
CENTRAL GLIA

Glial (neuroglial) cells vary considerably in type and number in different regions of the CNS. There are two major groups, macroglia (astrocytes and oligodendrocytes) and microglia, classified according to origin. Macrogia arise within the neural plate, in parallel with neurones, and constitute the great majority of glial cells. Their functions are diverse and are now known to extend beyond a passive supporting role (reviewed in He & Sun, 2007). Microglia are smaller cells, generally considered to be monocytic in origin, and are derived from haemopoietic tissue (see Fig. 3.21).

ASTROCYTES

Astrocytes are star-shaped glia (Fig. 3.10). Their processes, which ramify through the entire central neuropil (Fig. 3.11), are coupled functionally at gap junctions, forming an interconnected network which ensheathes all neurones, other than at synapses and along the myelinated segments of axons. Some astrocyte processes terminate as end-feet on the basal lamina of blood vessels, and at the pial surface, where they
form the glia limitans (glial limiting membrane).

**Fig. 3.10** Confocal micrograph of an astrocyte in an adult rat optic nerve, iontophoretically filled with an immunofluorescent dye by intracellular microinjection. (Prepared by Professor A Butt, Portsmouth, and Kate Colquhoun, formerly of Division of Physiology, GKT School of Medicine, London.)
Astrocytes have been divided into two subtypes, fibrous and protoplasmic, on morphological grounds. Fibrous astrocytes occur predominantly in white matter and protoplasmic astrocytes are found mainly in grey matter. The significance of these subtypes is unclear since there are few functional differences between fibrous and protoplasmic astrocytes. Astrocytes typically have a pale nucleus with a narrow rim of heterochromatin, although this is variable. Their cytoplasm is pale and contains glycogen, lysosomes, Golgi complexes and bundles of glial intermediate filaments that extend into their processes (these last are found particularly in fibrous astrocytes). Glial intermediate filaments are formed from glial fibrillary acidic protein (GFAP): its presence can be used clinically to identify tumour cells of glial origin.

Astrocytes are now thought to provide a network of communication, providing integration and regulation of function in the brain (reviewed in Fields 2004, Volterra & Meldolesi 2005). One form of communication, with other astrocytes, is via interconnecting low resistance gap junctional complexes. There is recent evidence that astrocytic (and other neural) gap junctions may be formed by a novel family of proteins, the pannexins (see p. 7). They signal to each other using intracellular calcium wave propagation, triggered by synaptically-released glutamate. Signalling presumably co-ordinates astrocyte functions that are essential for efficient neuronal activity, such as ion (particularly potassium) buffering; neurotransmitter uptake and metabolism (e.g. of excess glutamate, which is excitotoxic); membrane transport; the secretion of peptides, amino acids, trophic factors etc. The complexity of astrocytic function and dysfunction in neurological disorders is reviewed in Seifert et al (2006).

Injury to the CNS induces astrogliosis, seen as a local increase in the number and size of cells expressing GFAP, and in the production of an extensive meshwork of processes to form a glial scar. It is thought that the microenvironment of a glial scar, which may also include cells of oligodendrocyte lineage and myelin debris, plays an important role in inhibiting regrowth of damaged CNS axons.

Pituicytes are glial cells found in the neural parts of the pituitary gland, the infundibulum and neurohypophysis. They resemble astrocytes, but their processes
end mostly on endothelial cells in the neurohypophysis and tuber cinereum.

Blood–brain barrier

Proteins circulating in the blood enter most tissues of the body except those of the brain, spinal cord or peripheral nerves. This concept of a blood–brain or a blood–nerve barrier applies to many substances – some are actively transported across the blood–brain barrier, others are actively excluded. The blood–brain barrier is located at the capillary endothelium within the brain and is dependent upon the presence of tight junctions between endothelial cells coupled with a relative lack of transcytotic vesicular transport. The tightness of the barrier depends upon the close apposition of astrocytes, which direct the formation of endothelial tight junctions, to blood capillaries (reviewed in Abbott et al 2006) (Fig. 3.12, Fig. 3.13).

Fig. 3.12 Astrocytes (A) in rat brain, immunolabelled to show glial fibrillary acidic protein (brown). Fine processes form end-feet (E) on brain capillaries (C). Note that astrocytes have extremely dense, numerous processes: immunostaining only reveals a proportion of the processes. (Prepared by Mr Marios Hadjipavlou, King's College, London.)
The blood–brain barrier develops during embryonic life but may not be fully completed by birth. There are certain areas of the adult brain where the endothelial cells are not linked by tight junctions, which means that a free exchange of molecules occurs between blood and adjacent brain. Most of these areas are situated close to the ventricles and are known as circumventricular organs (p. 240). Elsewhere, unrestricted diffusion through the blood–brain barrier is only possible for substances that can cross biological membranes because of their lipophilic character. Lipophilic molecules may be actively re-exported by the brain endothelium.
Breakdown of the blood–brain barrier occurs when the brain is damaged by ischaemia or infection, and is also associated with primary and metastatic cerebral tumours. Reduced blood flow to a region of the brain alters the permeability and regulatory transport functions of the barrier locally: the increased stress on compromised endothelial cells results in leakage of fluid, ions, serum proteins and intracellular substances into the extracellular space of the brain. The integrity of the barrier can be evaluated clinically using CT and fMRI. Breakdown of the blood–brain barrier may be seen at postmortem in jaundiced patients who have had an infarction. Normally, the brain, spinal cord and peripheral nerves remain unstained by the bile post mortem, although the choroid plexus is often stained a deep yellow. However, areas of recent infarction (1–3 days) will also be stained by bile pigment because of the localized breakdown of the blood–brain barrier.
OLIGODENDROCYTES

Oligodendrocytes myelinate CNS axons and are most commonly seen as intrafascicular cells in myelinated tracts (Fig. 3.14, Fig. 3.15). They usually have round nuclei and their cytoplasm contains numerous mitochondria, microtubules and glycogen. They display a spectrum of morphological variation, from cells with large euchromatic nuclei and pale cytoplasm, to cells with heterochromatic nuclei and dense cytoplasm. Oligodendrocytes may enclose up to 50 axons in separate myelin sheaths, and the largest calibre axons are usually ensheathed on a 1 : 1 basis. Some oligodendrocytes are not associated with axons, and are either precursor cells or perineuronal (satellite) oligodendrocytes whose processes ramify around neuronal somata.

![Diagram of oligodendrocyte ensheathment](Image)

**Fig. 3.14** The ensheathment of a number of axons by the processes of an oligodendrocyte. The oligodendrocyte soma is shown in the centre and its myelin sheaths are unfolded to varying degrees to show their extensive surface area. *(Modified from Morell & Norton 1980 by Raine 1984, by permission.)*

Within tracts, interfascicular oligodendrocytes are arranged in long rows interspersed with single astrocytes at regular intervals. Since oligodendrocyte processes are radially aligned to the axis of each row, myelinated tracts typically consist of cables of axons myelinated by a row of oligodendrocytes running down the axis of each cable.

Oligodendrocytes originate from the ventricular neurectoderm and the subependymal layer in the fetus (p. 368), and continue to be generated from the subependymal plate postnatally. Stem cells migrate and seed into white and grey matter to form a pool of adult progenitor cells which may later differentiate to replenish lost oligodendrocytes, and possibly remyelinate pathologically demyelinated regions.

**Nodes of Ranvier and incisures of Schmidt–Lanterman**

The territory ensheathed by an oligodendrocyte (or Schwann cell) process defines an internode, the interval between internodes is called a node of Ranvier (Fig. 3.16) and the territory immediately adjacent to the nodal gap is a paranode, where loops of oligodendrocyte cytoplasm abut the axolemma. Nodal axolemma is contacted by fine filopodia of perinodal cells which have been shown in animal studies to have a presumptive adult oligodendrocyte progenitor phenotype: their function is unknown (reviewed in Butt et al 2005). Schmidt–Lanterman incisures are helical decompactions of internodal myelin where the major dense line of the myelin sheath splits to enclose a spiral of oligodendrocyte cytoplasm. Their structure suggests that they may play a role in the transport of molecules across the myelin sheath, but their function is not known.

![Fig. 3.16](image_url) A node of Ranvier (N) in the central nervous system. The pale-staining axon (A) is ensheathed by oligodendrocyte myelin (arrow), apart from a short, exposed region at the node. Toluidine blue stained resin section (rat tissue).

MYELIN AND MYELINATION

Myelin is formed by oligodendrocytes (CNS) and Schwann cells (PNS). A single oligodendrocyte may ensheathe up to 50 separate axons, depending upon calibre, whereas myelinating Schwann cells ensheathe axons on a 1:1 basis.

In general, myelin is laid down around axons above 2 µm diameter. However, the critical minimal axon diameter for myelination is smaller and more variable in the CNS than in the PNS (approximately 0.2 µm in the CNS compared with 1–2 µm in the PNS). There is considerable overlap between the size of the smallest myelinated and the largest unmyelinated axons, and so axonal calibre is unlikely to be the only factor in determining myelination. Moreover, the first axons to become ensheathed ultimately attain larger diameters than those that are ensheathed at a later date. There is a reasonable linear relationship between axon diameter and internodal length and myelin sheath thickness: as the sheath thickens from a few lamellae to up to 200, the axon may also grow from 1 to 15 µm in diameter. Internodal lengths increase about tenfold during the same time.

It is not known precisely how myelin is formed in either PNS or CNS, but in the CNS it has been shown recently to depend in part on expression of a protein (Wiskott–Aldrich syndrome protein family verprolin homologous; WAVE), which influences the actin cytoskeleton, oligodendrocyte lamellipodia formation and myelination (Kim et al 2006). The ultrastructural appearance of myelin is usually explained in terms of the spiral wrapping of an extensive, flat glial process (lamellipodium) around an axon, and the subsequent extrusion of cytoplasm from the sheath at all points other than incisures and paranodes. In this way, the compacted external surfaces of the plasma membrane of the ensheathing glial cell are thought to produce the minor dense lines, and the compacted inner cytoplasmic surfaces, the major dense lines, of the mature myelin sheath (Fig. 3.17). These lines, first described in early electron microscope studies of the myelin sheath, correspond to the intraperiod and period lines respectively defined in X-ray studies of myelin. The inner and outer zones of occlusion of the spiral process are continuous with the minor dense line and are called the inner and outer mesaxons.

![Image of myelin structure](image-url)
There are significant differences between central and peripheral myelin, reflecting the fact that oligodendrocytes and Schwann cells express different proteins during myelogenesis. The basic dimensions of the myelin membrane are different. CNS myelin has a period repeat thickness of 15.7 nm whereas PNS myelin has a period line thickness of 18.5 nm, and the major dense line space is approximately 1.7 nm in CNS myelin, compared with 2.5 nm in PNS myelin. Myelin membrane contains protein, lipid and water, which forms at least 20% of the wet weight. It is a relatively lipid-rich membrane and contains 70–80% lipid. All classes of lipid have been found; perhaps not surprisingly, the precise lipid composition of PNS and CNS myelin is different. The major lipid species are cholesterol (the commonest single molecule), phospholipids and glycosphingolipids. Minor lipid species include galactosylglycerides, phosphoinositides and gangliosides. The major glycolipids are galactocerebroside and its sulphate ester, sulphatide: these lipids are not unique to myelin, but they are present in characteristically high concentrations. CNS and PNS myelin also contain low concentrations of acidic glycolipids, which constitute important antigens in some inflammatory demyelinating states. Gangliosides, which are glycosphingolipids characterized by the presence of sialic acid (N-acetyleneuraminic acid), account for less than 1% of the lipid in myelin.

A relatively small number of protein species account for the majority of myelin protein. Some of these proteins are common to both PNS and CNS myelin, but others are different. Proteolipid protein (PLP) and its splice variant DM20 are found only in CNS myelin, whereas myelin basic protein (MBP) and myelin associated glycoprotein (MAG) occur in both. MAG is a member of the immunoglobulin supergene family, and is localized specifically at those regions of the myelin segment where compaction starts, namely, the mesaxons and inner periaxonal membranes, paranodal loops and incisures, in both CNS and PNS sheaths. It is thought to have a functional role in membrane adhesion.

In the developing CNS, axonal outgrowth precedes the migration of oligodendrocyte precursors, and oligodendrocytes associate with and myelinate axons after their phase of elongation: oligodendrocyte myelin gene expression is not dependent on axon-association. In marked contrast, Schwann cells in the developing PNS are associated with axons during the entire phase of axonal growth. Myelination does not occur simultaneously in all parts of the body in late fetal and early postnatal development. White matter tracts and nerves in the periphery have their own specific temporal patterns which relate to their degree of functional maturity.

Mutations of the major myelin structural proteins have now been recognized in a number of inherited human neurological diseases. As would be expected, these
mutations produce defects in myelination, and in the stability of nodal and paranodal architecture, which are consistent with the suggested functional roles of the relevant proteins in maintaining the integrity of the myelin sheath. The molecular organization of myelinated axons is described in Scherer & Arroyo (2002).
EPENDYMA

Ependymal cells line the ventricles (Fig. 3.18; see Fig. 3.11) and central canal of the spinal cord. They form a single-layered epithelium which varies from squamous to columnar in form. At the ventricular surface, cells are joined by gap junctions and occasional desmosomes. Their apical surfaces have numerous microvilli and cilia which contribute to the flow of CSF. There is considerable regional variation in the ependymal lining of the ventricles, but four major types have been described. These are: general ependyma which overlies grey matter; general ependyma which overlies white matter; specialized areas of ependyma in the third and fourth ventricles; choroidal epithelium.

The ependymal cells overlying areas of grey matter are cuboidal; each cell bears approximately 20 central apical cilia, surrounded by short microvilli. The cells are joined by gap junctions and desmosomes and do not have a basal lamina. Beneath them there may be a subependymal (or subventricular) zone, from two to three cells deep, consisting of cells which generally resemble ependymal cells. The capillaries beneath them have no fenestrations and few transcytotic vesicles, which is typical of the CNS. Where the ependyma overlies myelinated tracts of white matter, the cells are much flatter and few are ciliated. There are gap junctions and desmosomes between these cells, but their lateral margins interdigitate, unlike their counterparts overlying grey matter. No subependymal zone is present.

Specialized areas of ependymal cells called the circumventricular organs are found in four areas around the margins of the third ventricle, namely the lining of the median
eminence of the hypothalamus; the subcommissural organ; the subfornical organ and the vascular organ of the lamina terminalis. The area postrema, at the inferoposterior limit of the fourth ventricle, has a similar structure. In all of these sites the ependymal cells are only rarely ciliated and their ventricular surfaces bear many microvilli and apical blebs. They have numerous mitochondria, well-formed Golgi complexes and a rather flattened basal nucleus. They are joined laterally by tight junctions which form a barrier to the passage of materials across the ependyma, and by desmosomes. Many of the cells are tanyocytes (ependymal astrocytes) and have basal processes which project into the perivascular space surrounding the underlying capillaries. Significantly these capillaries are fenestrated and therefore do not form a blood–brain barrier. It is believed that neuropeptides can pass from nervous tissue into the CSF by active transport through the ependymal cells in these specialized areas, and in this way access a wide population of neurones via the permeable ependymal lining of the rest of the ventricle.

The ependyma is highly modified where it lies adjacent to the vascular layer of the choroid plexuses.

**Choroid plexus**

The choroid plexus forms the CSF and actively regulates the concentration of molecules in the CSF. It consists of highly vascularized masses of pia mater enclosed by pockets of ependymal cells. The ependymal cells resemble those of the circumventricular organs, except that they do not have basal processes, but form a cuboidal epithelium which rests on a basal lamina adjacent to the enclosed fold of meningeal pia mater and its capillaries (Fig. 3.19, Fig. 3.20). The cells have numerous long microvilli with only a few cilia interspersed between them. They also have many mitochondria, large Golgi complexes and basal nuclei, features that are consistent with their secretory activity: they produce most components of the CSF. They are linked by tight junctions that form a transepithelial barrier (a component of the blood–CSF barrier), and by desmosomes. Their lateral margins are highly folded.
Fig. 3.19 Choroid plexus within the lateral ventricle. Frond-like projections of vascular stroma derived from the pial meninges are covered with a low columnar epithelium which secretes cerebrospinal fluid. Mouse tissue, toluidine blue stained resin section.
The choroid plexus has a villous structure where the stroma is composed of pial meningeal cells, and contains fine bundles of collagen and blood vessels. Choroidal capillaries are lined by a fenestrated endothelium. During fetal life, erythropoiesis occurs in the stroma, which is occupied by bone marrow-like cells. In adult life, the stroma contains phagocytic cells, which, together with the cells of the choroid plexus epithelium, phagocytose particles and proteins from the ventricular lumen.

Age-related changes occur in the choroid plexus which can be detected by neuroimaging. Calcification of the choroid plexus can be detected by X-ray or CT scan in 0.5% of individuals in the first decade of life and in 86% in the eighth decade. The incidence of calcification rises sharply, from 35% of CT scans in the fifth decade to 75% in the sixth decade. Visible calcification is usually restricted to the glomus region of the choroid plexus, i.e. the vascular bulge in the choroid plexus as it curves to follow the anterior wall of the lateral ventricle into the temporal horn.
Microglia are small dendritic cells found throughout the CNS (Fig. 3.21) including the retina (p. 692). They are thought to be derived from fetal monocytes or their precursors; the haematogenous cells cross the walls of neural blood vessels and invade CNS tissue prenatally as amoeboid cells. Later they lose their motility and transform into typical microglia which bear branched processes that ramify in non-overlapping territories within the brain. All microglial domains, defined by their dendritic fields, are equivalent in size, and form a regular mosaic throughout the brain. The expression of microglia-specific antigens changes with age and many are downregulated when microglia attain the mature dendritic form.

Microglia have elongated nuclei with peripheral heterochromatin. Their scant cytoplasm is pale staining and contains granules, scattered cisternae of rough endoplasmic reticulum and Golgi complexes at both poles. Two or three primary processes stem from the opposite poles of each cell body and then branch repeatedly to form short terminal processes. The function of microglia in the normal brain is obscure. Like astrocytes, microglia are activated by both traumatic and ischaemic injury. In many diseases including Parkinson's disease, Alzheimer's disease, multiple sclerosis, acquired immunodeficiency syndrome (AIDS), amyotrophic lateral sclerosis (motor neurone disease) and paraneoplastic encephalitis, microglia become phagocytic and are actively involved in synaptic stripping and clearance of neuronal debris. Some transform into amoeboid, motile cells.
ENTRY OF INFLAMMATORY CELLS INTO THE BRAIN

Although the CNS has long been considered to be an immunologically privileged site, lymphocyte surveillance of the brain may be a normal, low-grade activity that is enhanced in disease. Lymphocytes can enter the brain in response to virus infections and as part of the autoimmune response in multiple sclerosis. Activated, but not resting, lymphocytes pass through the endothelium of small venules, a process that requires the expression of recognition and adhesion molecules (induced following cytokine activation) and subsequently migrate into the brain parenchyma. Within the CNS, microglia and astrocytes can be induced by T-cell cytokines to act as efficient antigen-presenting cells. After leaving the CNS, lymphocytes probably drain along lymphatic pathways to regional cervical lymph nodes.

Polymorphonuclear leukocyte entry into the CNS is less common than lymphocyte entry, but occurs in the early stages of infarction and autoimmune disease and, in particular, in pyogenic infections. They probably enter the nervous system by passing through the endothelial layer. Monocytes may follow similar pathways in the later stages of inflammation. Within the subarachnoid space, polymorphonuclear leukocytes and lymphocytes pass through the endothelium of large veins into the CSF during the inflammatory phase of meningitis.
PERIPHERAL NERVES

Afferent nerve fibres connect peripheral receptors to the CNS: they are derived from neuronal cell bodies located either in special sense organs (e.g. the olfactory epithelium) or in the sensory ganglia of the craniospinal nerves. Efferent nerve fibres connect the CNS to the effector cells and tissues: they are the peripheral axons of neurones with somata in the central grey matter.

Peripheral nerve fibres are grouped in widely variable numbers into bundles (fasciculi). The size, number and pattern of fasciculi vary in different nerves and at different levels along their paths (Fig. 3.22). Their number increases and their size decreases some distance proximal to a point of branching. Where nerves are subjected to pressure, e.g. deep to a retinaculum, fasciculi are increased in number but reduced in size, and the amount of associated connective tissue and degree of vascularity also increase. At these points, nerves may occasionally show a pink, fusiform dilatation, sometimes termed a pseudoganglion or gangliform enlargement.

Fig. 3.22  Transverse section through a human peripheral nerve, showing the arrangement of its connective tissue sheaths. Individual axons, myelinated and unmyelinated, are arranged in a small fascicle bounded by a perineurium. P, perineurium; Ep, epineurium; E, endoneurium.

PERIPHERAL NERVE FIBRES

Classification of peripheral nerve fibres is based on various parameters such as conduction velocity, function and fibre diameter. Of two classifications in common use,
the first divides fibres into three major classes, designated A, B and C, corresponding to peaks in the distribution of their conduction velocities. In man, group A fibres are subdivided into α, β, δ and γ subgroups: fibre diameter and conduction velocity are proportional in most fibres. Group A\(\alpha\) fibres are the largest and conduct most rapidly, and C fibres are the smallest and slowest.

The largest afferent axons (A\(\alpha\) fibres) innervate encapsulated cutaneous mechanoreceptors, Golgi tendon organs and muscle spindles, and some large alimentary enteroceptors. A\(\beta\) fibres form secondary endings on some muscle spindle (intrafusal) fibres and also innervate cutaneous and joint capsule mechanoreceptors. A\(\delta\) fibres innervate thermoreceptors, stretch-sensitive free endings, hair receptors and nociceptors, including those in dental pulp, skin and connective tissue. A\(\gamma\) fibres are exclusively fusimotor to plate and trail endings on intrafusal muscle fibres. B fibres are myelinated autonomic preganglionic efferent fibres. C fibres are unmyelinated and have thermoreceptive, nociceptive and interoceptive functions, including the perception of slow, burning pain and visceral pain. This scheme can be applied to fibres of both spinal and cranial nerves except perhaps those of the olfactory nerve, where the fibres form a uniquely small and slow group. The largest somatic efferent fibres (A\(\alpha\)) are up to 20 µm in diameter. They innervate extrafusal muscle fibres (at motor end plates) exclusively and conduct at a maximum of 120 m/s. Fibres to fast twitch muscles are larger than those to slow twitch muscle. Smaller (A\(\gamma\)) fibres of gamma motor neurones, and autonomic preganglionic (B) and postganglionic (C) efferent fibres conduct, in order, progressively more slowly (40 m/s – less than 10 m/s).

A different classification divides fibres into groups I–IV on the basis of their calibre; groups I–III are myelinated and group IV is unmyelinated. Group I fibres are large (12–22 µm), and include primary sensory fibres of muscle spindles (Group Ia) and smaller fibres of Golgi tendon organs (Group Ib). Group II fibres are the secondary sensory terminals of muscle spindles, with diameters of 6–12 µm. Group III fibres, 1–6 µm in diameter, have free sensory endings in the connective tissue sheaths around and within muscles and are nociceptive and, in skin, also thermosensitive. Group IV fibres are unmyelinated, with diameters below 1.5 µm: they include free endings in skin and muscle, and are primarily nociceptive.
CONNECTIVE TISSUE SHEATHS

Nerve trunks, whether uni- or multifascicular, are surrounded by an epineurium. Individual fasciculi are enclosed by a multilayered perineurium, which in turn surrounds the endoneurium or intrafascicular connective tissue (Fig. 3.22).

Epineurium

Epineurium is a condensation of loose (areolar) connective tissue derived from mesoderm. As a general rule, the more fasciculi present in a peripheral nerve, the thicker the epineurium. Epineurium contains fibroblasts, collagen (types I and III), and variable amounts of fat, and it cushions the nerve it surrounds. Loss of this protective layer may be associated with pressure palsies seen in wasted, bedridden patients. The epineurium also contains lymphatics (which probably pass to regional lymph nodes) and blood vessels, vasa nervorum, that pass across the perineurium to communicate with a network of fine vessels within the endoneurium.

Perineurium

Perineurium extends from the CNS–PNS transition zone to the periphery, where it is continuous with the capsules of muscle spindles and encapsulated sensory endings, but ends openly at unencapsulated endings and neuromuscular junctions. It consists of alternating layers of flattened polygonal cells (thought to be derived from fibroblasts) and collagen. It can often contain 15–20 layers of such cells, each layer enclosed by a basal lamina up to 0.5 µm thick. Within each layer the cells interdigitate along extensive tight junctions; their cytoplasm typically contains vesicles and bundles of microfilaments and their plasma membrane often shows evidence of pinocytosis. These features are consistent with the function of the perineurium as a metabolically active diffusion barrier; together with the blood–nerve barrier the perineurium is thought to play an essential role in maintaining the osmotic milieu and fluid pressure within the endoneurium.

Endoneurium

Strictly speaking, the term endoneurium is restricted to intrafascicular connective tissue and excludes the perineurial partitions within fascicles. Endoneurium consists of a fibrous matrix composed predominantly of type III collagen (reticulin) fibres, characteristically organized in fine bundles lying parallel to the long axis of the nerve, and condensed around individual Schwann cell–axon units and endoneurial vessels. The fibrous and cellular components of the endoneurium are bathed in endoneurial fluid at a slightly higher pressure than that outside in the surrounding epineurium. The major cellular constituents of the endoneurium are Schwann cells and endothelial
cells; minor components are fibroblasts (constituting approximately 4% of the total endoneurial cell population), resident macrophages and mast cells. Schwann cell–axon units and blood vessels are enclosed within individual basal laminae and therefore isolated from the other cellular and acellular components of the endoneurium.

Endoneurial arterioles have a poorly developed smooth muscle layer, and do not autoregulate well. In sharp contrast, epineurial and perineurial vessels have a dense perivascular plexus of peptidergic, serotoninergic and adrenergic nerves.
SCHWANN CELLS

Schwann cells are the major glial type in the PNS. In vitro they are fusiform in appearance. Both in vitro and in vivo, Schwann cells ensheathe peripheral axons, and myelinate those greater than 2 µm diameter. In a mature peripheral nerve, they are distributed along the axons in longitudinal chains: the precise geometry of their association depends on whether the axon is myelinated or unmyelinated. In myelinated axons the territory of a Schwann cell defines an internode.

The molecular phenotype of mature myelin-forming Schwann cells is different from that of mature non-myelinating Schwann cells. Adult myelin-forming Schwann cells are characterized by the presence of several myelin proteins, some, but not all, of which are shared with oligodendrocytes and central myelin. In contrast, expression of the low affinity neurotrophin receptor (p75^{NTR}) and GFAP intermediate filament protein (which differs from the CNS form in its post-translational modification), characterize adult non-myelin forming Schwann cells.

Schwann cells arise from multipotent cells of the very early migrating neural crest that can also give rise to peripheral neurones. Neuronal signals regulate many aspects of Schwann cell behaviour in developing and postnatal nerves. Axon-associated signals appear to control the proliferation of developing Schwann cells and their precursors; the developmentally programmed death of those precursors in order to match numbers of axons and glia within each peripheral nerve bundle; the production of basal laminae by Schwann cells; the induction and maintenance of myelination. Relatively little is known about either Schwann cell–axon or Schwann cell–Schwann cell signalling in normal nerves. An extensive literature supports the view that Schwann cells are key players in the acute injury response in the PNS, helping to provide a microenvironment that facilitates axonal regrowth. Few Schwann cells persist in chronically denervated nerves.

Unmyelinated axons

Unmyelinated axons (Fig. 3.23) are commonly 1.0 µm in diameter, although some may be 1.5 µm or even 2 µm in diameter. Groups of up to 10 small axons (0.15–2.0 µm in diameter) are enclosed within a chain of overlapping Schwann cells that is surrounded by a basal lamina. Within each Schwann cell, individual axons are usually sequestered from their neighbours by delicate processes of cytoplasm. Axons move between Schwann cell chains as they pass proximodistally along a nerve fasciculus. It seems likely, on the basis of quantitative studies in subhuman primates, that axons from adjacent cord segments may share Schwann cell columns: this phenomenon may play a role in the evolution of neuropathic pain after nerve injury. In the absence of a myelin sheath and nodes of Ranvier, conduction along unmyelinated axons is not saltatory but electrotonic, and the passage of impulses is therefore relatively slow (approximately 0.5–4.0 m/s).
Myelinated axons

Myelinated axons (Fig. 3.24) have a 1:1 relationship with their ensheathing Schwann cells. The territory of an individual Schwann cell defines an internode (Fig. 3.25): internodal length varies directly with the diameter of the fibre, from 150 to 1500 µm. The interval between two internodes is a node of Ranvier. In the PNS, the myelin sheaths on either side of a node terminate in asymmetrically swollen paranodal bulbs. Schwann cell cytoplasm only forms a continuous layer in the perinuclear (mid-internodal) and paranodal regions. Between these sites, internodal Schwann cytoplasm forms a delicate network over the inner (abaxonal) surface of the myelin sheath. The outer (adaxonal) layer of Schwann cell cytoplasm is frequently discontinuous, and axons are surrounded by a narrow periaxonal space (15–20 nm) which, although nominally part of the extracellular space, is functionally isolated from it at the paranodes. For further details, see Scherer & Arroyo (2002).

Many microtubules and neurofilaments are visible within the axoplasm. **B**, The arrangement of the axon, myelin sheath and Schwann cell cytoplasm at the node of Ranvier and in the paranodal bulbs.

(A, By courtesy of Professor Susan Standring, GKT School of Medicine, London. B, Redrawn from a figure provided by PL Williams and DN Landon.)

**Nodes of Ranvier**

PNS nodes of Ranvier (Fig. 3.25) are typically approximately 0.8–1.1 µm in length. The calibre of the nodal axon is characteristically reduced relative to that of the internodal axon: this is most marked in the largest calibre axons. Node gaps are filled with an amorphous gap substance and processes of Schwann cell cytoplasm, and are surrounded by a continuous basal lamina elaborated by the ensheathing Schwann cells. In large calibre axons the surfaces of the paranodal bulbs and of the underlying axon are fluted as they approach the nodes. Fluting produces grooves in the external surface of the myelin sheath that are filled by Schwann cell cytoplasm characterized by large numbers of mitochondria. In smaller fibres this arrangement is less obvious, although the paranodal cytoplasm usually contains mitochondria.

**Schmidt–Lanterman incisures**

Schmidt–Lanterman incisures are helical decompactions of internodal myelin that occur in every sheath, irrespective of thickness. At an incisure the major dense line of the myelin sheath splits to enclose a continuous spiral band of granular cytoplasm that passes between the abaxonal and adaxonal layers of Schwann cell cytoplasm. The minor dense line of the incisural myelin sheath separates to create a long channel that potentially connects the periaxonal space with the extracellular fluid in the endoneurium. The function of incisures is not known: their structure suggests that they may participate in transport of molecules across the myelin sheath.
SATELLITE CELLS

Many non-neuronal cells of the nervous system have been called satellite cells, including small round extracapsular cells in peripheral ganglia, ganglionic capsular cells, Schwann cells, any cell that is closely associated with neuronal somata, and precursor cells associated with striated muscle fibres (p. 117). Within the nervous system, the term is most commonly reserved for flat, epithelioid cells (ganglionic glial cells, capsular cells) that surround the neuronal somata of peripheral ganglia (Fig. 3.26). Their cytoplasm resembles that of Schwann cells, and their deep surfaces interdigitate with reciprocal infoldings in the membranes of the enclosed neurones. Capsular cells are succeeded by similar cells that enclose the initial part of the dendroaxonal process of unipolar sensory neurones in dorsal spinal ganglia, and these in turn are continuous with the Schwann cells that surround the peripheral and central processes of the neurones.

Fig. 3.26 Sensory neurones in a dorsal root ganglion (rat). Neurones (N) are typically variable in size but all are encapsulated by satellite cells (S). Myelinated fibres are seen above and below the neuronal somata. Toluidine blue stained resin section.

Enteric glia

Enteric nerves lack an endoneurium and so do not have the collagenous coats of other peripheral nerves. The enteric ganglionic neurones are supported by glia that closely resemble astrocytes: they contain more glial fibrillary acidic protein (GFAP)
than non-myelinating Schwann cells, and do not produce a basal lamina.

**Olfactory ensheathing glia**

Olfactory ensheathing glia share a common origin with olfactory receptor neurones in the olfactory placode. They ensheath olfactory sensory axons in a manner that is reminiscent of the relationship between Schwann cells and axons in very immature peripheral nerves, i.e. they surround, but do not segregate, bundles of up to 50 fine unmyelinated fibres to form approximately 20 fila olfactoria. Olfactory ensheathing glia accompany olfactory axons from the lamina propria of the olfactory epithelium to their synaptic contacts in the glomeruli of the olfactory bulbs. This unusual arrangement is unique: elsewhere in the nervous system the territories of peripheral and central glia are clearly demarcated at CNS–PNS transition zones.

Ensheathing glia, and the end-feet of astrocytes that lie between olfactory axon bundles, both contribute to the glia limitans at the pial surface of the olfactory bulbs. Ensheathing glia have a malleable phenotype, indeed there may be more than one subtype. Some express GFAP as fine cytoplasmic filaments, and some express p75NTR.
BLOOD SUPPLY OF PERIPHERAL NERVES

The blood vessels supplying a nerve end in a capillary plexus that pierces the perineurium. The branches of the plexus run parallel with the fibres, connected by short transverse vessels, forming narrow, rectangular meshes similar to those found in muscle. The blood supply of peripheral nerves is unusual. Endoneurial capillaries have atypically large diameters and intercapillary distances are greater than in many other tissues. Peripheral nerves have two separate, functionally independent vascular systems: an extrinsic system (regional nutritive vessels and epineurial vessels) and an intrinsic system (longitudinally running microvessels in the endoneurium). Anastomoses between the two systems produce considerable overlap between the territories of the segmental arteries. This unique pattern of vessels, together with a high basal nerve blood flow relative to metabolic requirements, means that peripheral nerves possess a high degree of resistance to ischaemia.

Blood–nerve barrier

Just as the neuropil within the CNS is protected by a blood–brain barrier, the endoneurial contents of peripheral nerve fibres are protected by a blood–nerve barrier and by the cells of the perineurium. The blood–nerve barrier operates at the level of the endoneurial capillary walls, where the endothelial cells are joined by tight junctions, are non-fenestrated and surrounded by continuous basal laminae. The barrier is much less efficient in dorsal root ganglia and autonomic ganglia and in the distal parts of peripheral nerves.
GANGLIA

Ganglia are aggregations of neuronal somata and are of varying form and size. They occur in the dorsal roots of spinal nerves; in the sensory roots of the trigeminal, facial, glossopharyngeal, vagal and vestibulocochlear cranial nerves; in autonomic nerves and in the enteric nervous system. Each ganglion is enclosed within a capsule of fibrous connective tissue and contains neuronal somata and neuronal processes. Some ganglia, particularly in the ANS, contain fibres from cell bodies that lie elsewhere in the nervous system and that either pass through, or terminate within, the ganglia.

Sensory ganglia

The sensory ganglia of dorsal spinal roots (Fig. 3.26) and the ganglia of the trigeminal, facial, glossopharyngeal and vagal cranial nerves are enclosed in periganglionic connective tissue that resembles the perineurium surrounding peripheral nerves. Ganglionic neurones are unipolar. They have spherical or oval somata of varying size, aggregated in groups between fasciculi of myelinated and unmyelinated nerve fibres. For each neurone, the single axodendritic process bifurcates into central and peripheral processes: in myelinated fibres the junction occurs at a node of Ranvier. The peripheral process reaches a sensory ending and, since it conducts impulses towards the soma, strictly speaking it functions as an elongated dendrite. However, since it has the typical structural and functional properties of a peripheral axon, it is conventionally described as an axon.

Each neuronal soma is surrounded by a capsule of glial satellite cells (see above). Each axodendritic process and its peripheral and central divisions, ensheathed by Schwann cells, lies outside the capsule. All of the cells in the ganglion lie within a delicate vascular connective tissue that is continuous with the endoneurium of the nerve root. Sensory ganglionic neurones are not confined to discrete craniospinal ganglia, and often occupy heterotopic positions, either singly or in small groups, distal or proximal to their ganglia.

Herpes zoster

Primary infection with the varicella zoster virus causes chickenpox. Following recovery, the virus remains dormant within dorsal root ganglia: its reactivation leads to shingles, which involves the dermatome(s) supplied by the affected sensory nerve(s). Severe pain and a rash similar to chickenpox, often confined to one of the divisions of the trigeminal nerve, or to a spinal nerve dermatome, are diagnostic. Herpes zoster involving the geniculate ganglion compresses the facial nerve and results in a lower motor neurone facial paralysis, known as Ramsay Hunt syndrome. Occasionally, if the vestibulocochlear nerve becomes involved, there is vertigo, tinnitus and some deafness.

Autonomic ganglia

Autonomic ganglia are largely relay stations. Their neurones are multipolar and have dendritic trees on which preganglionic autonomic motor axons synapse (Fig. 3.27). The neurones are surrounded by a mixed neuropil of afferent and efferent fibres, dendrites, synapses and non-neural cells. There is considerable variation in the ratio
of pre- and postganglionic fibres in different types of ganglion. Thus preganglionic sympathetic axons may synapse with many postganglionic neurones for the wide dissemination and perhaps amplification of sympathetic activity, a feature not found to the same degree in parasympathetic ganglia. Dissemination may also be achieved by connections with ganglionic interneurones or by the diffusion within the ganglion of transmitter substances produced either locally (paracrine effect) or elsewhere (endocrine effect). A small fraction of the fibres within a ganglion are either efferent fibres en route to another ganglion, or are afferent fibres from the viscera and glands: none of these fibres will synapse in the ganglion.

**Fig. 3.27** Autonomic ganglion (human) on a peripheral nerve (PN) in adipose connective tissue. Neuronal somata (N) and a nerve fibre layer (NF) are visible within the ganglion.

Most neurones of autonomic ganglia have somata ranging from 25–50 µm; a less frequent type is smaller, 15–20 µm, and often clustered in groups. Dendritic fields of these multipolar neurones are complex and dendritic glomeruli have been observed in many ganglia. Clusters of small granular adrenergic vesicles occupy the soma and dendrites, probably representing the storage of catecholamines. Ganglionic neurones receive many axodendritic synapses from preganglionic nerve fibres; axosomatic synapses are less numerous. Postganglionic fibres commonly arise from the initial stem of a large dendrite and produce few or no collateral processes.

**Enteric ganglia**

The enteric nervous system is composed of ganglionic neurones (Fig. 3.28) and associated nerves serving different functions, including regulation of gut motility and
mucosal transport (see Chs 15 and 60). Extrinsic autonomic fibres supply the gut wall and, together with intrinsic enteric ganglionic neurones, and the endocrine and cardiovascular systems, they integrate the activities of the digestive system either as a result of interaction with enteric neurones (e.g. via vagal fibres), or the direct regulation of the local blood flow (via postganglionic sympathetic fibres).

![Fig. 3.28 Enteric ganglion (outlined) of the myenteric (Auerbach’s) plexus between the inner circular and outer longitudinal layers of smooth muscle (M) in the wall of the human intestine. An enteric ganglionic neurone is arrowed.](image)

Enteric ganglionic neurones are predominantly peptidergic or monoaminergic and can be classified accordingly. Other neurones express nitric oxide synthase and release NO. There are regional differences in the numbers of ganglia and the classes of neurone they contain. For example, myenteric plexus ganglia are less frequent in oesophageal smooth muscle (1.5 per cm) than in the small and large intestines (approximately 10 per cm length of bowel). Oesophageal enteric neurones all coexpress vasoactive polypeptide (VIP) and neuropeptide Y (NPY), whereas gastrin- and somatostatin-containing fibres are rare. In contrast, gastrin and somatostatin-containing neurones are abundant in the small and large intestines, and although both types are present, very few VIP neurones coexpress NPY.

Correlations can be made between some phenotypic classes of enteric neurone and their functional properties, although much remains undetermined. Cholinergic neurones are excitatory, cause muscular contraction and mainly project orally. NO-releasing neurones are generally larger and project for longer distances, mainly anally. They are inhibitory neurones, some of which also express VIP, and they
promote muscular relaxation.
Although the nervous, neuroendocrine and endocrine systems all operate by intercellular communication, they differ in the mode, speed and degree or localization of the effects produced. The autonomic nervous system uses impulse conduction and neurotransmitter release to transmit information, and the responses induced are rapid and localized. The dispersed neuroendocrine system uses only secretion. It is slower and the induced responses are less localized, because the secretions, e.g. neuromediators, can act either on contiguous cells, or on groups of nearby cells reached by diffusion, or on distant cells via the bloodstream. Many of its effector molecules operate in both the nervous system and the neuroendocrine system. The endocrine system proper, which consists of clusters of cells and discrete, ductless, hormone-producing glands, is even slower and less localized, although its effects are specific and often prolonged. These regulatory systems overlap in function, and can be considered as a single neuroendocrine regulator of the metabolic activities and internal environment of the organism, acting to provide conditions in which it can function successfully. Neural and neuroendocrine axes appear to cooperate to modulate some forms of immunological reaction: the extensive system of vessels, circulating hormones and nerve fibres that link the brain with all viscera are thought to constitute a neuroimmune network (Fig. 3.29). For further reading see Furness (2006); Shepherd et al (2005).
The ways in which the nervous system, neuroendocrine system and immune system are integrated, demonstrated in the intestine. Neurocrine signals from enteric neuroendocrine cells and signals from immune defence cells (e.g. lymphocytes, macrophages and mast cells) act on other cells of those systems and on neurones with sensory endings in the intestinal wall, either locally or at a distance. Some neuronal soma lie within enteric ganglia in the gut wall, others have their bodies in peripheral ganglia. Neuronal signals may act locally, be transmitted to the CNS or enter a reflex pathway via sympathetic ganglia.

Some cells can take up and decarboxylate amine precursor compounds (amine precursor uptake and decarboxylation or APUD cells). They are characterized by dense-core cytoplasmic granules (see Fig. 2.6), similar to the neurotransmitter vesicles seen in some types of neuronal terminal. The group includes cells described as chromaffin cells (phaeochromocytes), derived from neuroectoderm and innervated by preganglionic sympathetic nerve fibres. Chromaffin cells synthesize and secrete catecholamines (dopamine, noradrenaline or adrenaline). Their name refers to the finding that their cytoplasmic store of catecholamines is sufficiently concentrated to give an intense yellow-brown colouration, the positive chromaffin reaction, when they are treated with aqueous solutions of chromium salts, particularly potassium dichromate. Classic chromaffin cells include clusters of cells in the suprarenal medulla; the para-aortic bodies, which secrete noradrenaline; paraganglia (see Ch. 15); certain cells in the carotid bodies; small groups of cells irregularly dispersed among the paravertebral sympathetic ganglia, splanchnic nerves and prevertebral autonomic plexuses.

The alimentary tract contains a large population of cells of a similar type (previously called neuroendocrine or enterochromaffin cells) in its wall. These cells act as sensory...
transducers, activating intrinsic and extrinsic primary afferent neurones via their release of 5-hydroxytryptamine (5-HT). The neonatal respiratory tract contains a prominent system of neuroendocrine cells, both dispersed and aggregated (neuroepithelial bodies): the numbers of both types decline during childhood. Merkel cells in the basal epidermis of the skin store neuropeptides which they release to associated nerve endings in response to pressure. Experimental animal studies have revealed 5-HT-containing intraepithelial paraneurones in the urothelial lining of the urethra: these cells are thought to relay information from the luminal surface of the urethra to underlying sensory nerves.

A number of descriptions and terms have been applied to cells of this system in the older literature. They include: clear cells (so named because of their poor staining properties in routine preparations); argentaffin cells (reduce silver salts); argyrophil cells (absorb silver); small intensely fluorescent cells; peptide-producing cells (particularly of the hypothalamus, hypophysis, pineal and parathyroid glands and placenta); Kulchitsky cells in the lungs; paraneurones. Many cells of the dispersed (or diffuse) neuroendocrine system, DNES, are derived embryologically from the neural crest. Some, in particular cells from the alimentary system, are now known to be endodermal in origin. For further reading, see Day and Salzet (2002).
SENSORY ENDINGS

GENERAL FEATURES OF SENSORY RECEPTORS

There are three major forms of sensory receptor, neuroepithelial, epithelial and neuronal (Fig. 3.30).

A neuroepithelial receptor is a neurone with a soma lying near a sensory surface and an axon that conveys sensory signals into the CNS to synapse on second order neurones. This is an evolutionarily primitive arrangement, and the only example in man is the sensory neurone of the olfactory epithelium.

An epithelial receptor is a cell that is modified from a non-nervous sensory epithelium and innervated by a primary sensory neurone with a soma lying near the CNS. Examples are epidermal Merkel cells, auditory receptors and taste buds. When activated, this type of receptor excites its neurone by neurotransmission across a synaptic gap.

A neuronal receptor is a primary sensory neurone that has a soma in a craniospinal ganglion and a peripheral axon ending in a sensory terminal. All cutaneous sensors (with the exception of Merkel cells) and proprioceptors are of this type: their sensory terminals may be encapsulated or linked to special mesodermal or ectodermal structures to form a part of the sensory apparatus. The extraneural cells are not necessarily excitable, but create an appropriate environment for the excitation of the neuronal process.

The receptor stimulus is transduced into a graded change of electrical potential at the receptor surface (receptor potential), and this initiates an all-or-none action potential that is transmitted to the CNS. This may occur either in the receptor, when this is a neurone, or partly in the receptor and partly in the neurone that innervates it, in the case of epithelial receptors. Transduction varies with the modality of the stimulus, and usually causes depolarization of the receptor membrane (or hyperpolarization, in the retina). In mechanoreceptors, transduction may involve the deformation of membrane structure, which causes strain- or voltage-sensitive transducing protein molecules to open ion channels. In chemoreceptors, receptor action may resemble that for ACh at neuromuscular junctions. Visual receptors share similarities with chemoreceptors: light causes changes in receptor proteins, which activate G proteins, resulting in the release of second messengers and altered membrane permeability.

The quantitative responses of sensory endings to stimuli vary greatly and increase the flexibility of the functional design of sensory systems. Although increased excitation with increasing stimulus level is a common pattern (‘on’ response), some receptors respond to decreased stimulation (‘off’ response).
Even unstimulated receptors show varying degrees of spontaneous background activity against which an increase or decrease in activity occurs with changing levels of stimulus. In all receptors studied, when stimulation is maintained at a steady level, there is an initial burst (the dynamic phase) followed by a gradual adaptation to steady level (the static phase). Though all receptors show these two phases, one or other may predominate, providing a distinction between rapidly adapting endings which accurately record the rate of stimulus onset, and slowly adapting endings which signal the constant amplitude of a stimulus, e.g. position sense. Dynamic and static phases are reflected in the amplitude and duration of the receptor potential and also in the frequency of action potentials in the sensory fibres. The stimulus strength necessary to elicit a response in a receptor, i.e. its threshold level, varies greatly between receptors, and provides an extra level of information about stimulus strength.

For further information on sensory receptors, see Nolte (2002).
FUNCTIONAL CLASSIFICATION OF RECEPTORS

Receptors have been classified in several ways. They may be classified by the modalities to which they are sensitive, such as mechanoreceptors (which are responsive to deformation, e.g. touch, pressure, sound waves, etc.), chemoreceptors, photoreceptors and thermoreceptors. Some receptors are polymodal, i.e. they respond selectively to more than one modality: they usually have high thresholds and respond to damaging stimuli associated with irritation or pain (nociceptors).

Another widely used classification divides receptors on the basis of their distribution in the body into exteroceptors, proprioceptors and interoceptors. Exteroceptors and proprioceptors are receptors of the somatic afferent components of the nervous system, while interoceptors are receptors of the visceral afferent pathways.

Exteroceptors respond to external stimuli and are found at, or close to, body surfaces. They can be subdivided into the general or cutaneous sense organs and special sensory organs. General sensory receptors include free and encapsulated terminals in skin and near hairs. Special sensory organs are the olfactory, visual, acoustic, vestibular and taste receptors.

Proprioceptors respond to stimuli to deeper tissues, especially of the locomotor system, and are concerned with detecting movement, mechanical stresses and position. They include Golgi tendon organs, neuromuscular spindles, Pacinian corpuscles, other endings in joints, and vestibular receptors. Proprioceptors are stimulated by the contraction of muscles, movements of joints and changes in the position of the body. They are essential for the coordination of muscles, the grading of muscular contraction, and the maintenance of equilibrium.

Interoceptors are found in the walls of the viscera, glands and vessels, where their terminations include free nerve endings, encapsulated terminals and endings associated with specialized epithelial cells. Nerve terminals are found in the layers of visceral walls and the adventitia of blood vessels, but the detailed structure and function of many of these endings are not well-established. Encapsulated (lamellated) endings occur in the heart, adventitia, and mesenteries. Free terminal arborizations occur in the endocardium, the endomysium of all muscles, and connective tissue generally. Visceral nerve terminals are not usually responsive to stimuli which act on exteroceptors, and do not respond to localized mechanical and thermal stimuli. Tension produced by excessive muscular contraction or by visceral distension often causes pain, particularly in pathological states, which is frequently poorly localized and of a deep-seated nature. Visceral pain is often referred to the corresponding dermatome (see Fig. 15.12). Polymodal nociceptors (irritant receptors) respond to a variety of stimuli such as noxious chemicals or
damaging mechanical stimuli. They are mainly the free endings of fine, unmyelinated fibres that are widely distributed in the epithelia of the alimentary and respiratory tracts: they may initiate protective reflexes.

Interoceptors include vascular chemoreceptors, e.g. the carotid body, and baroceptors, which are concerned with the regulation of blood flow and pressure and the control of respiration.
FREE NERVE ENDINGS

Sensory endings that branch to form plexuses occur in many sites (Fig. 3.30). They occur in all connective tissues, including those of the dermis, fasciae, capsules of organs, ligaments, tendons, adventitia of blood vessels, meninges, articular capsules, periosteum, perichondrium, Haversian systems in bone, parietal peritoneum, walls of viscera and the endomysium of all types of muscle. They also innervate the epithelium of the skin, cornea, buccal cavity, and the alimentary and respiratory tracts and their associated glands. Within epithelia, free sensory endings lack Schwann cell ensheathment and are enveloped instead by epithelial cells. Afferent fibres from free terminals may be myelinated or unmyelinated but are always of small diameter and low conduction velocity. When afferent axons are myelinated, their terminal arborizations are not. These terminals serve several sensory modalities. In the dermis, they may be responsive to moderate cold or heat (thermoreceptors); light mechanical touch (mechanoreceptors); damaging heat, cold or deformation (unimodal nociceptors); damaging stimuli of several kinds (polymodal nociceptors). Similar fibres in deeper tissues may also signal extreme conditions, which are experienced, as with all nociceptors, as pain. Free endings in the cornea, dentine and periosteum may be exclusively nociceptive.

Special types of free ending are associated with epidermal structures in the skin. They include terminals associated with hair follicles (peritrichial receptors) which branch from myelinated fibres in the deep dermal cutaneous plexus: the number, size and form of the endings are related to the size and type of hair follicle innervated. These endings respond mainly to movement when hair is deformed and belong to the rapidly adapting mechanoreceptor group.

Merkel tactile endings lie either at the base of the epidermis or around the apical ends of some hair follicles, and are innervated by large myelinated axons. Each axon expands into a disc that is applied closely to the base of a Merkel cell in the basal layer of the epidermis. The cells, which are believed to be derived from the neural crest, contain many large (50–100 nm) dense-cored vesicles, presumably containing transmitters, which are concentrated near the junction with the axon. Merkel endings are slow-adapting mechanoreceptors and are responsive to sustained pressure and sensitive to the edges of applied objects.
ENCAPSULATED ENDINGS

Encapsulated endings are a major group of special endings that includes lamellated corpuscles of various kinds (e.g. Meissner’s, Pacinian), Golgi tendon organs, neuromuscular spindles and Ruffini endings (Fig. 3.30). They exhibit considerable variety in their size, shape and distribution, but share a common feature, in that each axon terminal is encapsulated by non-excitable cells.

**Meissner’s corpuscles**

Meissner’s corpuscles are found in the dermal papillae of all parts of the hand and foot, the anterior aspect of the forearm, the lips, palpebral conjunctiva and mucous membrane of the apical part of the tongue. They are most concentrated in thick hairless skin, especially of the finger pads, where there may be up to 24 corpuscles per cm$^2$ in young adults. Mature corpuscles are cylindrical in shape, approximately 80 μm long and 30 μm across, with their long axes perpendicular to the skin surface. Each corpuscle has a connective tissue capsule and central core composed of a stack of flat modified Schwann cells (Fig. 3.31). Meissner’s corpuscles are rapidly adapting mechanoreceptors, sensitive to shape and textural changes in exploratory and discriminatory touch: their acute sensitivity provides the neural basis for reading Braille text.
Pacinian corpuscles are situated subcutaneously in the palmar and plantar aspects of the hand and foot and their digits; the external genitalia; arm; neck; nipple; periostea; interosseous membranes; near joints, and within the mesenteries. They are oval, spherical or irregularly coiled and measure up to 2 mm in length and 100–500 µm or more across: the larger ones are visible to the naked eye. Each corpuscle has a capsule, an intermediate growth zone and a central core that contains an axon terminal. The capsule is formed by approximately 30 concentrically arranged lamellae of flat cells approximately 0.2 µm thick (Fig. 3.32). Adjacent cells overlap and successive lamellae are separated by an amorphous proteoglycan matrix that contains circularly orientated collagen fibres, closely applied to the surfaces of the lamellar cells. The amount of collagen increases with age. The intermediate zone is cellular and its cells become incorporated into the capsule or core, so that it is not clearly defined in mature corpuscles. The core consists of approximately 60 bilateral, compacted lamellae lying on both sides of a central nerve terminal.
Each corpuscle is supplied by a myelinated axon, which initially loses its myelin sheath and subsequently loses its ensheathing Schwann cell at its junction with the core. The naked axon runs through the central axis of the core and ends in a slightly expanded bulb. It is in contact with the innermost core lamellae, is transversely oval and sends short projections of unknown function into clefts in the lamellae. The axon contains numerous large mitochondria, and minute vesicles, approximately 5 nm in diameter, which aggregate opposite the clefts. The cells of the capsule and core lamellae are thought to be specialized fibroblasts but some may be Schwann cells. Elastic fibrous tissue forms an overall external capsule to the corpuscle. Pacinian corpuscles are supplied by capillaries that accompany the axon as it enters the capsule.

Pacinian corpuscles act as very rapidly adapting mechanoreceptors. They respond only to sudden disturbances and are especially sensitive to vibration. The rapidity may be partly due to the lamellated capsule acting as a high pass frequency filter, damping slow distortions by fluid movement between lamellar cells. Groups of corpuscles respond to pressure changes, e.g. on grasping or releasing an object.

**Ruffini endings**

Ruffini endings are slowly adapting mechanoreceptors. They are found in the dermis of thin, hairy skin, where they function as dermal stretch receptors and are responsive to maintained stresses in dermal collagen. They consist of the highly branched, unmyelinated endings of myelinated afferents. They ramify between bundles of collagen fibres within a spindle-shaped structure which is enclosed partly by a fibrocellular sheath derived from the perineurium of the nerve. Ruffini endings appear electrophysiologically similar to Golgi tendon organs, which they resemble, although they are less organized structurally. Similar structures appear in joint capsules (see below).

**Golgi tendon organs**
Golgi tendon organs are found mainly near musculotendinous junctions (Fig. 3.33), where more than 50 may occur at any one site. Each terminal is related closely to a group of muscle fibres (up to 20) as they insert into the tendon. Golgi tendon organs are approximately 500 µm long and 100 µm in diameter, and consist of small bundles of tendon fibres enclosed in a delicate capsule. The collagen bundles (intrafusal fasciculi) are less compact than elsewhere in the tendon, the collagen fibres are smaller and the fibroblasts larger and more numerous. A single, thickly myelinated 1b afferent nerve fibre enters the capsule and divides. Its branches, which may lose their ensheathing Schwann cells, terminate in leaf-like enlargements containing vesicles and mitochondria, which wrap around the tendon. A basal lamina or process of Schwann cell cytoplasm separates the nerve terminals from the collagen bundles that constitute the tendon. Golgi tendon organs are activated by passive stretch of the tendon, but are much more sensitive to active contraction of the muscle. They are important in providing proprioceptive information that complements the information coming from neuromuscular spindles. Their responses are slowly adapting and they signal maintained tension.
Fig. 3.33 The structure and innervation of a Golgi tendon organ. For clarity the perineurium and endoneurium have been omitted to show the distribution of nerve fibres ramifying between the collagen fibre bundles of the tendon.
NEUROMUSCULAR SPINDLES

Neuromuscular spindles are essential for the control of muscle contraction. Each spindle contains a few small, specialized intrafusal muscle fibres, innervated by both sensory and motor nerve fibres (Fig. 3.34, Fig. 3.35). The whole is surrounded equatorially by a fusiform spindle capsule of connective tissue, consisting of an outer perineurial-like sheath of flattened fibroblasts and collagen and an inner sheath that forms delicate tubes around individual intrafusal fibres (Fig. 3.36). A gelatinous fluid rich in glycosaminoglycans fills the space between the two sheaths.

Fig. 3.34 A neuromuscular spindle, showing nuclear bag and nuclear chain fibres within the spindle capsule (green); these are innervated by the sensory anulospiral and ‘flower spray’ afferent fibre endings (blue) and by the γ and β fusimotor (efferent fibre) endings (red). The β efferent fibres are collaterals of fibres innervating extrafusal slow twitch muscle cells (pink, bottom left).
Fig. 3.35  Nuclear bag and nuclear chain fibres in a neuromuscular spindle. Dynamic β- and γ-efferents innervate dynamic bag 1 intrafusal fibres, whereas static β- and γ-efferents innervate static bag 2 and nuclear chain intrafusal fibres.
There are usually 5–14 intrafusal fibres (the number varies between muscles) and two major types of fibre, nuclear bag and nuclear chain fibres, which are distinguished by the arrangement of nuclei in their sarcoplasm. In nuclear bag fibres, an equatorial cluster of nuclei makes the fibre bulge slightly, whereas the nuclei in nuclear chain fibres form a single axial row. Nuclear bag fibres are greater in diameter than chain fibres and extend beyond the surrounding capsule to the endomysium of nearby extrafusal muscle fibres. Nuclear chain fibres are attached at their poles to the capsule or to the sheaths of nuclear bag fibres.

The intrafusal fibres resemble typical skeletal muscle fibres, except that the zone of myofibrils is thin around the nuclei. One subtype of nuclear bag fibre (dynamic bag 1) generally lacks M lines, possesses little sarcoplasmic reticulum and has an abundance of mitochondria and oxidative enzymes, but little glycogen. A second subtype of bag fibre (static bag 2) has distinct M lines and abundant glycogen. Nuclear chain fibres have marked M lines, sarcoplasmic reticulum and T-tubules, and abundant glycogen, but few mitochondria. These variations reflect the contractile properties of different intrafusal fibres (Boyd 1985).

Muscle spindles receive two types of sensory innervation via the unmyelinated terminations of large myelinated axons. Primary (anulospiral) endings are equatorially placed and form spirals around the nucleated parts of intrafusal fibres. They are the endings of large sensory fibres (Group Ia afferents), each of which sends branches to a number of intrafusal muscle fibres. Each terminal lies in a deep sarcolemmal groove in the spindle plasma membrane beneath its basal lamina. Secondary (flowerspray) endings, which may be spray-shaped or anular, are largely confined to nuclear chain fibres, and are the branched terminals of somewhat thinner myelinated (Group II) afferents. They are varicose and spread in a narrow band on both sides of the primary endings. They lie close to the sarcolemma, though not in grooves. In essence primary endings are rapidly adapting, while secondary endings have a regular, slowly adapting, response to static stretch.

There are three types of motor endings in muscle spindles. Two are from fine,
myelinated, fusimotor (γ) efferents and one is from myelinated (β) efferent collaterals of axons that supply extrafusal slow twitch muscle fibres. The fusimotor efferents terminate nearer the equatorial region where their terminals either resemble the motor end-plates of extrafusal fibres (plate endings) or are more diffuse (trail endings). Stimulation of the fusimotor and β efferents causes contraction of the intrafusal fibres and consequently, activation of their sensory endings.

Muscle spindles signal the length of extrafusal muscle both at rest and throughout contraction and relaxation, the velocity of their contraction and changes in velocity. These modalities may be related to the different behaviours of the three major types of intrafusal fibre and their sensory terminals. The sensory endings of one type of nuclear bag fibre (dynamic bag 1) are particularly concerned with signalling rapid changes in length that occur during movement, whilst those of the second bag fibre type (static bag 2), are less responsive to movement. The afferents from chain fibres have relatively slowly adapting responses at all times. These elements can therefore detect complex changes in the state of the extrafusal muscle surrounding spindles and can signal fluctuations in length, tension, velocity of length change and acceleration. Moreover, they are under complex central control: efferent (fusimotor) nerve fibres, by regulating the strength of contraction, can adjust the length of the intrafusal fibres and thereby the responsiveness of spindle sensory endings. In summary, the organization of spindles allows them to monitor muscle conditions actively in order to compare intended and actual movements, and to provide a detailed input to spinal, cerebellar, extrapyramidal and cortical centres about the state of the locomotor apparatus.
JOINT RECEPTORS

The arrays of receptors situated in and near articular capsules provide information on the position, movements and stresses acting on joints. Structural and functional studies have demonstrated at least four types of joint receptor: their proportions and distribution vary with site. Three are encapsulated endings, the fourth a free terminal arborization.

Type I endings are encapsulated corpuscles of the slowly adapting mechanoreceptor type and resemble Ruffini endings. They lie in the superficial layers of the fibrous capsules of joints in small clusters and are innervated by myelinated afferent axons. Being slowly adapting, they provide awareness of joint position and movement, and respond to patterns of stress in articular capsules. They are particularly common in joints where static positional sense is necessary for the control of posture (e.g. hip, knee).

Type II endings are lamellated receptors, and resemble small versions of the large Pacinian corpuscles found in general connective tissue. They occur in small groups throughout joint capsules, particularly in the deeper layers and other articular structures (e.g. the fat pad of the temporomandibular joint). They are rapidly adapting, low-threshold mechanoreceptors, sensitive to movement and pressure changes, and they respond to joint movement and transient stresses in the joint capsule. They are supplied by myelinated afferent axons, but are probably not involved in the conscious awareness of joint sensation.

Type III endings are identical to Golgi tendon organs in structure and function: they occur in articular ligaments, but not in joint capsules. They are high-threshold, slowly adapting receptors and may serve, at least in part, to prevent excessive stresses at joints by reflex inhibition of the adjacent muscles. They are innervated by large myelinated afferent axons.

Type IV endings are free terminals of myelinated and unmyelinated axons that ramify in articular capsules, the adjacent fat pads and around the blood vessels of the synovial layer. They are high-threshold, slowly adapting receptors and are thought to respond to excessive movements, providing a basis for articular pain.
The most intensively studied effector endings are those that innervate muscle, particularly skeletal muscle. All neuromuscular (myoneural) junctions are axon terminals of somatic motor neurones. They are specialized for the release of neurotransmitter on to the sarcolemma of skeletal muscle fibres, causing a change in their electrical state which leads to contraction. Each axon branches near its terminal to innervate from several to hundreds of muscle fibres, the number depending on the precision of motor control required.

The detailed structure of a motor terminal varies with the type of muscle innervated. Two major types of ending are recognized, innervating either extrafusal muscle fibres, or the intrafusal fibres of neuromuscular spindles. In the former type, each axonal terminal usually ends midway along a muscle fibre in a discoidal motor end-plate (Fig. 3.37), and usually initiates action potentials that are rapidly conducted to all parts of the muscle fibre. In the latter type, the axon gives off numerous branches that form a cluster of small expansions extending along the muscle fibre; in the absence of propagated muscle excitation, these excite the fibre at several points. Both types of ending are associated with a specialized receptive region of the muscle fibre, the sole plate, where a number of muscle cell nuclei are grouped within the granular sarcoplasm.
Fig. 3.37 The neuromuscular junction. A, Whole-mount preparation of teased skeletal muscle fibres (pale, faintly striated, diagonally orientated structures). The terminal part of the axon (silver-stained, brown) branches to form motor end-plates on adjacent muscle fibres. The sole plate recesses in the sarcolemma, into which the motor end-plates fit, are demonstrated by the presence of acetylcholinesterase (shown by enzyme histochemistry, blue). B, Diagrammatic representation of the axonal motor end-plate and the deeply infolded sarcolemma. C, Electron micrograph showing the expanded motor end-plate of the axon filled with vesicles containing synaptic transmitter (ACh) (above); the deep infoldings of the sarcolemmal sole plate (below) form subsynaptic gutters.

(A By courtesy of Dr Norman Gregson, Division of Neurology, GKT School of Medicine, London; C By courtesy of Professor DN Landon, Institute of Neurology, University College London.)
The sole plate contains numerous mitochondria, endoplasmic reticulum and Golgi complexes. The terminal branches of the axon are plugged into shallow grooves in the surface of the sole plate (primary clefts), from where numerous pleats extend for a short distance into the underlying sarcoplasm (secondary clefts) (Fig. 3.37B,C). The axon terminal contains mitochondria and many clear, 60 nm spherical vesicles similar to those in presynaptic boutons, which are clustered over the zone of membrane apposition. It is ensheathed by Schwann cells whose cytoplasmic projections extend into the synaptic cleft. The plasma membranes of the axon terminal and the muscle cell are separated by a 30–50 nm gap and an interposed basal lamina which follows the surface folding of the sole plate membrane into the secondary clefts. The basal lamina contains specialized components including specific isoforms of type IV collagen and laminin and the heparan sulphate proteoglycan, agrin. Endings of fast and slow twitch muscle fibres (p. 111) differ in detail: the sarcolemmal grooves are deeper, and the presynaptic vesicles more numerous, in the fast fibres.

Junctions with skeletal muscle are cholinergic; the release of ACh changes the ionic permeability of the muscle fibre. Clustering of ACh receptors at the neuromuscular junction depends in part on the presence in the muscle basal lamina of agrin, which is secreted by the motor neurone, and is important in establishing the post-junctional molecular machinery. When the depolarization of the sarcolemma reaches a particular threshold, it initiates an all-or-none action potential in the sarcolemma, which is then propagated rapidly over the whole cell surface and also deep within the fibre via the invaginations (T-tubules) of the sarcolemma (p. 108), causing contraction. The amount of ACh released by the arrival of a single nerve impulse is sufficient to trigger an action potential. However, because ACh is very rapidly hydrolysed by the enzyme AchE, present at the sarcolemmal surface of the sole plate, a single nerve impulse only gives rise to one muscle action potential, i.e. there is a one-to-one relationship between neural and muscle action potentials. Thus the contraction of a muscle fibre is controlled by the firing frequency of its motor neurone.

Neuromuscular junctions are partially blocked by high concentrations of lactic acid, as in some types of muscle fatigue.
AUTONOMIC MOTOR TERMINATIONS

Autonomic neuromuscular junctions differ in several important ways from the skeletal neuromuscular junction and from synapses in the CNS and PNS. There is no fixed junction with well defined pre- and post-junctional specializations. Unmyelinated, highly branched, postganglionic autonomic axons become beaded or varicose as they reach the effector smooth muscle. These varicosities are not static but move along axons. They are packed with mitochondria and vesicles containing neurotransmitters which are released from the varicosities during conduction of an impulse along the axon. The distance (cleft) between the varicosity and smooth muscle membrane varies considerably depending on the tissue, from 20 nm in densely innervated structures such as the vas deferens to 1–2 µm in large elastic arteries. Unlike skeletal muscle, the effector tissue is a muscle bundle rather than a single cell. Gap junctions between individual smooth muscle cells are low resistance pathways which allow electronic coupling and the spread of activity within the effector bundle: they vary in size from punctate junctions to junctional areas of more than 1 µm in diameter.

Adrenergic sympathetic postganglionic terminals contain dense-cored vesicles. Cholinergic terminals, which are typical of all parasympathetic and some sympathetic endings, contain clear spherical vesicles like those in the motor end-plates of skeletal muscle. A third category of autonomic neurones has non-adrenergic, non-cholinergic endings which contain a wide variety of chemicals with transmitter properties. Conjugated purine (ATP, a nucleoside), is probably the neurotransmitter at these terminals, which are thus classed as purinergic. For further reading on purinergic signalling, see Burnstock (2006). Typically, their axons contain large, 80–200 nm, dense opaque vesicles, congregated in varicosities at intervals along axons. Such terminals are formed in many sites, including the external muscle layers and sphincters of the alimentary tract, lungs, walls of blood vessels, urogenital tract and in the CNS (see Chapter 15). In the intestinal wall, neuronal somata lie in the myenteric plexus, and their axons spread caudally for a few millimetres, mainly to innervate circular muscle. Purinergic neurones are under cholinergic control from preganglionic sympathetic neurones, via postganglionic sympathetic fibres. Their endings mainly hyperpolarize smooth muscle cells, causing relaxation, e.g. preceding peristaltic waves, opening sphincters and, probably, causing reflex distension in gastric filling.

Autonomic efferents also innervate glands, myoepithelial cells, adipose and lymphoid tissues.
CNS–PNS TRANSITION ZONE

The transition between CNS and PNS usually occurs some distance from the point at which nerve roots emerge from the brain or the spinal cord. The segment of root that contains components of both CNS and PNS tissue is called the CNS–PNS transition zone (TZ). All axons in the PNS, other than postganglionic autonomic neurones, cross such a TZ. Macroscopically, as a nerve root is traced towards the spinal cord or the brain, it splits into several thinner rootlets which may, in turn, subdivide into minirootlets. The TZ is located within either rootlet or minirootlet (Fig. 3.38). The arrangement of roots and rootlets varies according to whether the root trunk is ventral, dorsal or cranial. Thus, in dorsal roots, the main root trunk separates into a fan of rootlets and minirootlets which enter the spinal cord in sequence along the dorsolateral sulcus. In certain cranial nerves the minirootlets come together central to the TZ and enter the brain as a stump of white matter.

Microscopically, the TZ is characterized by an axial CNS compartment surrounded by a PNS compartment. The zone lies more peripherally in sensory than in motor nerves, but in both, the apex of the TZ is described as a glial dome, whose convex surface is usually directed distally. The centre of the dome consists of fibres with a typical CNS organization, surrounded by an outer mantle of astrocytes (corresponding to the glia limitans). From this mantle, numerous glial processes project into the endoneurial compartment of the peripheral nerve where they interdigitate with its Schwann cells. The astrocytes form a loose reticulum through which axons pass. Peripheral myelinated axons usually cross the zone at a node of Ranvier, which is here termed a PNS–CNS compound node.

A novel cell type, the boundary cap (BC) cell, has been described recently in avian and mammalian species. BCs are derived from the neural crest and form transient clusters in the presumptive dorsal root TZ of the embryonic spinal cord: they are thought to prevent cell mixing at this interface and to help dorsal root ganglion afferents navigate their path to targets in the spinal cord. It has been proposed that within dorsal root ganglia, BC-derived cells are the progenitors of neurones, mainly nociceptive afferents, satellite cells and all Schwann cell precursors that migrate into
the dorsal roots (see Maro et al 2004).
CONDUCTION OF THE NERVOUS IMPULSE

All cells generate a steady electrical potential across their plasma membranes (a membrane potential) by maintaining ionic concentrations inside the cell that differ from the extracellular fluid (Fig. 3.39). In neurones this membrane potential is known as the resting potential, and at approximately \(-80\) mV (potential inside the cell measured relative to the outside of the cell), it is similar to that of non-excitable cells. However, unlike non-excitable cells, neurones receive, conduct, and transmit information across their surfaces using minute fluctuations in membrane potential that result from changes in transmembrane ion fluxes. Sodium or, in some sites, calcium, entry causes depolarization of the cell, while chloride influx or potassium efflux results in hyperpolarization. Plasma membrane permeability to these ions is altered by the opening or closing of ion-specific transmembrane channels, triggered by chemical or electrical stimuli.

![Fig. 3.39](image)

**Fig. 3.39** The types of change in electrical potential that can be recorded across the cell membrane of a motor neurone at the points indicated. Excitatory and inhibitory synapses on the surfaces of the dendrites and soma cause local graded changes of potential which summate at the axon hillock and may initiate a series of all-or-none action potentials, which in turn are conducted along the axon to the effector terminals.

Chemically triggered ionic fluxes may be either direct, where the chemical agent (neurotransmitter) binds to the channel itself to cause it to open, or indirect, where the
neurotransmitter is bound by a transmembrane receptor molecule that activates a complex second messenger system within the cell to open separate transmembrane channels. Electrically induced changes in membrane potential depend on the presence of voltage-sensitive ion channels which, when the transmembrane potential reaches a critical level, open to allow the influx or efflux of specific ions. In all cases, the channels remain open only transiently, and the numbers which open and close determine the total flux of ions across the membrane.

The types and concentrations of transmembrane channels and related proteins, and therefore the electrical activity of the membranes, vary in different parts of the cell. Dendrites and neuronal somata depend mainly on neurotransmitter action and show graded potentials, whereas axons have voltage-gated channels that give rise to action potentials.

In graded potentials, a flow of current occurs when a synapse is activated: the influence of an individual synapse on the membrane potential of neighbouring regions decreases with distance. Thus synapses on the distal tips of dendrites may, on their own, have relatively little effect on the membrane potential of the cell body. The electrical state of a neurone therefore depends on many factors, including the numbers and positions of thousands of excitatory and inhibitory synapses, their degree of activation, and the branching pattern of the dendritic tree and geometry of the cell body. The integrated activity directed toward the neuronal cell body is converted to an output directed away from the soma at the site where the axon leaves the cell body, the axon hillock. Voltage sensitive channels are concentrated at the axon hillock (unlike the dendrites or soma), and when this region is sufficiently depolarized, an action potential is generated and is subsequently conducted along the axon.

**ACTION POTENTIAL**

The action potential is a brief, self-propagating reversal of membrane polarity. It depends on an initial influx of sodium ions which causes a reversal of polarity to about +40 mV, followed by a rapid return towards the resting potential as potassium ions flow out (the detailed mechanism differs somewhat between CNS and PNS). The rapid reversal process is completed in approximately 0.5 msec, followed by a slower recovery phase of up to 5 msec, when the resting potential is fully restored. Once the axon hillock reaches threshold, propagation of the action potential is independent of the initiating stimulus, thus the size and duration of action potentials are always the same (described as all-or-none) for a particular neurone, no matter how much a stimulus may exceed the threshold value.

Once initiated, an action potential spreads spontaneously and at a relatively constant velocity, within the range of 4–120 m/s. Conduction velocity depends on a number of factors related to the way in which the current spreads, e.g. axonal cross-sectional area, the numbers and positioning of ion channels, and membrane capacitance (influenced particularly by the presence of myelin). In axons lacking myelin, action potential conduction is analogous to a flame moving along a fuse. Just as each segment of fuse is ignited by its upstream neighbour, each segment of axon membrane is driven to threshold by the depolarization of neighbouring membrane. Sodium channels within the newly depolarized segment open and positively charged sodium ions enter, driving the local potential inside the axon toward positive values.
This inward current in turn depolarizes the neighbouring, downstream, nondepolarized membrane, and the cyclic propagation of the action potential is completed.

Myelinated fibres are electrically insulated by their myelin sheaths along most of their lengths, except at nodes of Ranvier. The distance between nodes, referred to as the internodal distance, is directly related to axon diameter and varies between 0.2 and 2.0 mm. Voltage-gated sodium channels are clustered at nodes, and the nodal membrane is the only place where high densities of inward sodium current can be generated across the axon membrane. Like conduction in unmyelinated axons, conduction in myelinated axons is self-propagating, but instead of physically adjacent regions of membrane acting to excite one another, it is the depolarization occurring in the neighbouring upstream node that excites a node to threshold. Reaching threshold causes the sodium channels at the node to open and generate inward sodium current, but instead of this acting on the adjacent membrane, the high resistance and low capacitance of the myelin sheath directs the current toward the next downstream node, exciting it to threshold and completing the cycle. The action potential thus jumps from node to node, a process known as saltatory conduction, which greatly increases the conduction velocity.

A number of disorders of the CNS and PNS include demyelination as a characteristic feature. Perhaps most common amongst these is multiple sclerosis, which is characterized by primary demyelination at scattered sites within the white matter of the CNS (it is now recognized that axonal loss also contributes to the progression of multiple sclerosis). Primary demyelination is the loss of the myelin sheath with axonal preservation, and is usually segmental, ie. it rarely extends along the entire length of an affected axon. The phenomenon is associated with conduction block because the newly exposed, previously internodal, axolemma contains relatively few voltage-sensitive Na\(^+\) channels. There is experimental evidence that conduction can be restored in some demyelinated axons, and experimental and clinical evidence that remyelinated axons can conduct at near normal speeds, because even though their sheaths are thinner than the original myelin sheaths, the safety factor (i.e. the factor by which the outward current at a quiescent node next to an excited node exceeds the minimum current required to evoke a response) is greater than 1. The myelin loss that occurs in the early stages of Wallerian degeneration in both CNS and PNS, usually distal to a site of trauma but also in response to a prolonged period of ischaemia or exposure to a neuronotoxic substance, is accompanied by axonal degeneration (the term secondary demyelination is sometimes used to describe this form of myelin loss).

In both myelinated and unmyelinated fibres there is an irreducible interval at the end of an action potential, termed the refractory period, during which another action potential cannot be triggered. This determines the maximum frequency at which action potentials can be conducted along a nerve fibre: its value differs in different neurones and affects the amount of information which can be carried by an individual fibre.

Axonal conduction is naturally unidirectional, from dendrites and soma to axon terminals. When an action potential reaches the axonal terminals, it causes depolarization of the presynaptic membrane and as a result, quanta of neurotransmitter (which correspond to the content of individual vesicles) are released to change the degree of excitation of the next neurone, muscle fibre or glandular cell. For further information, see Kandel et al (2000).

CHAPTER 4 – Blood, lymphoid tissues and haemopoiesis

In postnatal life blood cells are formed in the bone marrow. Haemopoiesis produces red cells (erythrocytes), and a wide variety of defensive cells (white blood cells, or leukocytes). The latter include neutrophil, eosinophil and basophil granulocytes, B lymphocytes and monocytes. T lymphocytes develop in the thymus from bone marrow-derived progenitors. Platelets are produced in the bone marrow as cellular fragments of megakaryocytes. Only erythrocytes and platelets are generally confined to the blood vascular system, whereas all leukocytes can leave the circulation and enter extravascular tissues. The numbers of cells doing so increases greatly during inflammation caused by local infections and diseases.

The lymphoid tissues are the thymus, lymph nodes, spleen and the lymphoid follicles associated mainly with the alimentary and respiratory tracts. Lymphocytes populate lymphoid tissues and are concerned with various types of immune defence. Lymphoid tissue also contains supportive stromal cells which are non-haemopoietic in origin (e.g. thymic epithelium), non-haemopoietic follicular dendritic cells of lymph nodes and splenic follicles, haemopoietically-derived interdigitating dendritic cells, and macrophages of the mononuclear phagocyte system. Dendritic cells and blood monocyte-derived macrophages are found additionally in most tissues and organs where they function as immunostimulatory antigen-presenting cells (APCs).

CELLS OF PERIPHERAL BLOOD

BLOOD

Blood is an opaque fluid with a viscosity greater than that of water (mean relative viscosity 4.75 at 18°C), and a specific gravity of 1.06 at 15°C. It is bright red when oxygenated, in the systemic arteries, and dark red to purple when deoxygenated, in systemic veins. Blood is a mixture of a clear liquid, plasma, and cellular elements, and consequently the hydrodynamic flow of blood in vessels behaves in a complex manner that is not entirely predictable by simple Newtonian equations.

Plasma

Plasma is a clear, yellowish fluid which contains many substances in solution or suspension: low molecular weight solutes give a mean freezing-point depression of 0.54°C. Plasma contains high concentrations of sodium and chloride ions, potassium, calcium, magnesium, phosphate, bicarbonate, traces of many other ions, glucose, amino acids and vitamins. The colloids include high molecular weight plasma proteins, e.g. clotting factors, particularly prothrombin; immunoglobulins and complement proteins involved in immunological defence; glycoproteins, lipoproteins, polypeptide and steroid hormones and globulins for the transport of hormones and iron. Since most of the metabolic activities of the body are reflected in the plasma composition, its routine chemical analysis is of great diagnostic importance.

The precipitation of the protein fibrin from plasma to form a clot (Fig. 4.1) is
initiated by the release of specific materials from damaged cells and blood platelets in the presence of calcium ions. If blood or plasma samples are allowed to stand, they will separate into a clot and a clear yellowish fluid, the serum. Clot formation is prevented by removal of calcium ions, e.g. by addition of citrate, oxalate or various organic calcium chelators (EDTA, EGTA) to the sample. Heparin is also widely used as an anticlotting agent, because it interferes with another part of the complex series of chemical interactions which lead to fibrin clot formation.
Fig. 4.1 Erythrocytes enmeshed in filaments of fibrin in a clot.

ERYTHROCYTES

Erythrocytes (red blood cells, red blood corpuscles [RBC]) account for the largest proportion of blood cells (99% of the total number), with normal values of $4.1–6.0 \times 10^6/\mu l$ in adult males and $3.9–5.5 \times 10^6/\mu l$ in adult females. Polycythaemia (increased red cell mass) can occur in individuals living at high altitude, or pathologically in conditions resulting in arterial hypoxia. Reduction in red cell mass (anaemia) has many underlying causes but in rare instances can be due to structural defects in erythrocytes (see below).

Each erythrocyte is a biconcave disc (Fig. 4.1, Fig. 4.2) with a mean diameter in dried smear preparations of 7.1 µm; in fresh preparations the mean diameter is 7.8 µm, decreasing slightly with age. Mature erythrocytes lack nuclei. They are pale red by transmitted light, with paler centres because of their biconcave shape. The properties of their cell coat cause them to adhere to one another by their rims to form loose piles of cells (rouleaux). In normal blood, a few cells assume a shrunken star-like, crenated form: this shape can be reproduced by placing normal biconcave erythrocytes in a hypertonic solution, which causes osmotic shrinkage. In hypotonic solutions erythrocytes take up water and become spherical; they may eventually lyse to release their haemoglobin (haemolysis), leaving red cell ghosts.
Erythrocytes have a limiting plasma membrane which encloses mainly a single protein, haemoglobin, as a 33% solution. The plasma membrane of erythrocytes is 60% lipid and glycolipid, and 40% protein and glycoprotein. More than 15 classes of protein are present, including two major types. Glycophorins A and B (each with a molecular mass of approximately 50 kDa) span the membrane, and their negatively charged carbohydrate chains project from the outer surface of the cell. Their sialic acid groups confer most of the fixed charge on the cell surface. A second transmembrane macromolecule, band 3 protein, forms an important anion channel, exchanging bicarbonate for chloride ions across the membrane and allowing the release of CO$_2$ in the lungs. The ABO blood group antigens are all membrane glycolipids.

The shape of the erythrocyte is largely determined by the filamentous protein dimer, spectrin, a name which reflects its original isolation from red cell ghosts. Spectrin dimers associate as tetramers through their head regions, and are attached to the cytoplasmic domain of the anion carrier, band 3 protein, via ankyrin. Other proteins, including tropomyosin, tropomodulin and short actin filaments form junctional complexes which link spectrin to glycophorin transmembrane proteins, forming a stabilizing cytoskeletal network. This gives the membrane great flexibility: red cells are deformable but regain their biconcave shape and dimensions after passing through the smallest capillaries, which are 4 µm in diameter. Erythrocyte membrane flexibility also contributes to the normally low viscosity of blood. Defects in the cytoskeleton occur in autosomal dominant disorders (some cases of elliptocytosis result from mutations in spectrin and of spherocytosis from ankyrin dysfunction) which result in abnormalities of red cell shape, membrane fragility, premature destruction of
erythrocytes in the spleen and haemolytic anaemia.

Fetal erythrocytes up to the fourth month of gestation differ markedly from those of adults, in that they are larger, are nucleated and contain a different type of haemoglobin (HbF). After this time they are progressively replaced by the adult type of cell.

**Haemoglobin**

Haemoglobin (Hb) is a globular protein with a molecular mass of 67 kDa. It consists of globulin molecules bound to haem, an iron-containing porphyrin group. The oxygen-binding power of haemoglobin is provided by the iron atoms of the haem groups, and these are maintained in the ferrous (Fe^{++}) state by the presence of glutathione within the erythrocyte. The haemoglobin molecule is a tetramer, made up of four subunits, each a coiled polypeptide chain holding a single haem group. In normal blood, five types of polypeptide chain can occur, namely: α, β and two β-like polypeptides, γ and δ. A third, β-like η chain is restricted to early fetal development. Each haemoglobin molecule contains two α-chains and two others, so that several combinations, and hence a number of different types of haemoglobin molecule, are possible. For example, haemoglobin A (HbA), which is the major adult class, contains 2α- and 2β-chains; a variant, HbA₂ with 2α and 2δ chains, accounts for only 2% of adult haemoglobin. Haemoglobin F (HbF), found in fetal and early postnatal life, consists of 2α- and 2γ-chains. Adult red cells normally contain less than 1% of HbF.

In the pathological genetic condition thalassaemia, only one type of chain is expressed normally, the mutant chain being absent or present at much reduced levels. Thus, a molecule may contain 4 α-chains (β-thalassaemia) or, more commonly, 4 β-chains (α-thalassaemia) where individuals affected carry haemoglobin H (HbH). In haemoglobin S (HbS) of sickle-cell disease, a point mutation in the β-chain gene (valine substituted for glutamine) causes a major alteration in the behaviour of the red cell and its oxygen-carrying capacity.

**Lifespan**

Erythrocytes last between 100 and 120 days before being destroyed. As erythrocytes age they become increasingly fragile, and their surface charges decrease as their content of negatively charged membrane glycoproteins diminishes. The lipid content of their membranes also reduces. Aged erythrocytes are eventually ingested by the macrophages of the spleen and liver sinusoids, usually without prior lysis, and are hydrolysed in phagocytic vacuoles where the haemoglobin is split into its globulin and porphyrin moieties. Globulin is further degraded to amino acids which pass into the general amino acid pool. Iron is removed from the porphyrin ring and either transported in the circulation bound to transferrin and used in the synthesis of new haemoglobin in the bone marrow, or stored in the liver as ferritin or haemosiderin. The remainder of the haem group is converted in the liver to bilirubin and excreted in the bile.

The recognition of effete erythrocytes by macrophages appears to depend in part on the exposure of normally inaccessible parts of membrane proteins, enabling autoantibodies to these erythrocyte senescence antigens to bind to them and flag them for macrophage removal. Red cells are destroyed at the rate of $5 \times 10^{11}$ cells a
day and are normally replaced from the bone marrow (see Fig. 4.12) at the same rate.

Fig. 4.12 The origins and lineage relationships of haemopoietically-derived cells of the immune system. Mature cells and selected progenitors (all human) are illustrated (magnifications vary). The dendritic cell was cultured from peripheral blood, immunolabelled to show HLA-DR and photographed using Nomarski optics. The megakaryocyte and erythroblast are from a bone marrow smear, stained with MGG; the remaining cells illustrated are from peripheral blood smears (Wright's stain), sections of connective tissue (plasma cell, mast cell), bone (osteoclast) and lung alveolus (macrophage). Platelets (one is arrowed) are subcellular fragments of bone marrow megakaryocytes. Note that circulating small lymphocytes cannot be classified further with routine staining methods. For further explanation of cellular structure and staining properties, see the text.

**Blood groups**

Over 300 red cell antigens are recognizable with specific antisera. They can interact
with naturally occurring or induced antibodies in the plasma of recipients of an unmatched transfusion, causing agglutination and lysis of the erythrocytes. Erythrocytes of a single individual can carry several different types of antigen, each type belonging to an antigenic system in which a number of alternative antigens are possible in different persons. So far, 19 major groups have been identified. They vary in their distribution frequencies between different populations, and include the ABO, Rhesus, MNS, Lutheran, Kell, Lewis, Duffy, Kidd, Diego, Cartwright, Colton, Sid, Scianna, Yt, Aubergier, Li, Xg, Indian and Dombrock systems. Clinically, the ABO and Rhesus groups are of most importance.

In the ABO system, two allelic genes are inherited in simple Mendelian fashion. Thus the genome may be homozygous and carry the AA complement, the blood group being A, or the BB complement which gives blood group B, or it may carry neither (OO), producing blood group O. In the heterozygous condition the following combinations can occur: AB (blood group AB), AO (blood group A) and BO (blood group B).

Individuals with group AB blood lack antibodies to both A and B antigens, and so can be transfused with blood of any group: they are termed universal recipients. Conversely, those with group O, universal donors, can give blood to any recipient, since anti-A and anti-B antibodies in the donated blood are diluted to insignificant levels. Normally, however, blood is only transfused between persons with precisely corresponding groups, because anomalous antibodies of the ABO system are occasionally found in blood and may cause agglutination or lysis. The anti-ABO agglutinins, unlike those of the Rhesus system, belong to the immunoglobulin M (IgM) class and do not cross the placenta during pregnancy.

The Rhesus antigen system is determined by three sets of alleles, namely Cc, Dd and Ee: the most important clinically is Dd. Inheritance of the Rh factor also obeys simple Mendelian laws and it is therefore possible for a Rhesus-negative mother to bear a Rhesus-positive child. Fetal Rh antigens can, under these circumstances, stimulate the production of anti-Rh antibodies by the mother: since these belong to the immunoglobulin G (IgG) class of antibodies they are able to cross the placental barrier (generally late in the last trimester) and cause agglutination of fetal erythrocytes. In the first such pregnancy little damage usually occurs because anti-Rh antibodies are present only at low levels, but in subsequent Rh-positive pregnancies massive destruction of fetal red cells (haemolytic disease of the newborn) may result, causing fetal or neonatal death. Sensitization of the maternal immune system can also result from abortion or miscarriage, or even occasionally amniocentesis, which may introduce fetal antigens into the maternal circulation. Treatment is by exchange transfusion of the neonate or, prophylactically, by giving Rh-immune (anti-D) serum to the mother after the first Rh-positive pregnancy, which destroys the fetal Rh antigen in her circulation before sensitization can occur.

Leukocytes also bear highly polymorphic antigens encoded by allelic gene variants. These belong to the group of major histocompatibility complex (MHC) antigens, also termed human leukocyte antigens (HLA) in man. HLA Class I antigens are expressed by all nucleated cells. Class II antigen expression is more restricted outside the immune system, but is inducible on many parenchymal cell types e.g. after exposure to interferon. HLA Class I and II antigens play important roles in cell–cell interactions in the immune system, particularly in the presentation of antigens to T lymphocytes by
APCs.
LEUKOCYTES

Leukocytes (white blood cells) belong to at least five different categories (see Fig. 4.12), and are distinguishable by their size, nuclear shape and cytoplasmic inclusions. In practice, leukocytes are often divided into two main groups, namely those with prominent stainable cytoplasmic granules, the granulocytes, and those without.

Granulocytes

This group consists of eosinophil granulocytes, with granules which bind acidic dyes such as eosin; basophil granulocytes, with granules which bind basic dyes strongly; and neutrophil granulocytes, with granules which stain only weakly with either type of dye. Granulocytes (Fig. 4.3) all possess irregular or multilobed nuclei and belong to the myeloid series of blood cells (p. 77 see Fig. 4.12).

![Neutrophil and basophil granulocytes in a renal glomerular capillary](image)

**Fig. 4.3** Neutrophil (N) and basophil (B) granulocytes within a renal glomerular capillary in a human kidney biopsy. The neutrophil nucleus is more segmented (four lobes are visible) and the granules are smaller and more electron-dense than in the basophil.

Neutrophil granulocytes

Neutrophil granulocytes (neutrophils), are also referred to as polymorphonuclear
leukocytes (polymorphs) because of their irregularly segmented (multilobed) nuclei. They form the largest proportion of the white blood cells (40–75% in adults, with a normal count of 2500–7500/µl) and have a diameter of 12–14 µm. The cells may be spherical in the circulation, but they can flatten and become actively motile within the extracellular matrix of connective tissues.

The numerous cytoplasmic granules are heterogeneous in size, shape and content, but all are membrane-bound and contain hydrolytic and other enzymes. Two major types can be distinguished according to their developmental origin and contents. Non-specific or primary (azurophilic) granules are formed early in neutrophil maturation. They are relatively large (0.5 µm) spheroidal lysosomes containing myeloperoxidase, acid phosphatase, elastase and several other enzymes. Specific or secondary granules are formed later, and occur in a wide range of shapes including spheres, ellipsoids and rods. These contain strong bacteriocidal components including alkaline phosphatase, lactoferrin and collagenase, none of which are found in primary granules. Conversely, secondary granules lack peroxidase and acid phosphatase. Some enzymes, e.g. lysozyme, are present in both types of granule.

In mature neutrophils the nucleus is characteristically multilobed with up to six (usually three or four) segments joined by narrow nuclear strands: this is known as the segmented stage. Less mature cells have fewer lobes. The earliest to be released under normal conditions are juveniles (band or stab cells) in which the nucleus is an unsegmented crescent or band. In certain clinical conditions, even earlier stages in neutrophil formation, when cells display indented or rounded nuclei (metamyelocytes or myelocytes) may be released from the bone marrow. In mature cells the edges of the nuclear lobes are often irregular. In females 3% of the nuclei of neutrophils show a conspicuous ‘drumstick’ formation which represents the sex chromatin of the inactive X chromosome (Barr body). Neutrophil cytoplasm contains few mitochondria but abundant cytoskeletal elements, including actin filaments, microtubules and their associated proteins, all characteristic of highly motile cells.

Neutrophils are important in the defence of the body against microorganisms. They can phagocytose microbes and small particles in the circulation and, after extravasation, they carry out similar activities in other tissues. They function effectively in relatively anaerobic conditions, relying largely on glycolytic metabolism, and they fulfil an important role in the acute inflammatory phase of tissue injury, responding to chemotaxins released by damaged tissue. Phagocytosis of cellular debris or invading microorganisms is followed by fusion of the phagocytic vacuole, first with specific granules, whose pH is reduced to 5.0 by active transport of protons, then with non-specific (primary) granules, which complete the process of bacterial killing and digestion. Actively phagocytic neutrophils are able to reduce oxygen enzymatically to form reactive oxygen species including superoxide radicals and hydrogen peroxide, which enhance bacterial destruction.

Phagocytosis is greatly facilitated by circulating antibodies to molecules such as bacterial antigens which the body has previously encountered. Antibodies coat the antigenic target and bind the plasma complement protein, C1, to their non-variable Fc regions. This activates the complement cascade, which involves some 20 plasma proteins synthesized mainly in the liver, and completes the process of opsonization. The complement cascade involves the sequential cleavage of the complement proteins into a large fragment, which generally binds to the antigenic surface, and a
small bioactive fragment which is released. The final step is the recognition of complement by receptors on the surfaces of neutrophils (and macrophages), which promotes phagocytosis of the organism.

Neutrophils are short-lived; they spend some 6–7 hours circulating in the blood and a few days in connective tissues. The number of circulating neutrophils varies, and often rises during episodes of acute bacterial infection. They die after carrying out their phagocytic role: dead neutrophils, bacteria, tissue debris (including tissue damaged by neutrophil enzymes and toxins) and interstitial fluid form the characteristic, greenish-yellow pus of infected tissue. The colour is derived from the natural colour of neutrophil myeloperoxidase.

Granules may also be inappropriately released from neutrophils. Their enzymes are implicated in various pathological conditions, e.g. rheumatoid arthritis, where tissue destruction and chronic inflammation occur.

**Eosinophil granulocytes**

Eosinophil granulocytes (eosinophils) are similar in size (12–15 µm), shape and motile capacity to neutrophils, but are present only in small numbers in normal blood (100–400/µl). The nucleus has two prominent lobes connected by a thin strand of chromatin. Their cytoplasmic specific granules are uniformly large (0.5 µm) and give the living cell a slightly yellowish colour. The cytoplasm is packed with granules which are spherical or ellipsoid and membrane-bound. The core of each granule is composed of a lattice of major basic protein, which is responsible for its strong eosinophilic staining properties. The surrounding matrix contains several lysosomal enzymes including acid phosphatase, ribonuclease, phospholipase and a myeloperoxidase unique to eosinophils.

Like other leukocytes, eosinophils are motile. When suitably stimulated, they are able to pass into the extravascular tissues from the circulation. They are typical minor constituents of the dermis, and of the connective tissue components of the bronchial tree, alimentary tract, uterus and vagina. The total lifespan of these cells is a few days, of which some 10 hours is spent in the circulation, and the remainder in the extravascular tissues.

Eosinophil numbers rise (eosinophilia) in worm infestations and also in certain allergic disorders, and it is thought that they evolved as a primary defence against parasitic attack. They have surface receptors for IgE which bind to IgE-antigen complexes, triggering phagocytosis and release of granule contents. However, they are only weakly phagocytic and their most important function is the destruction of parasites too large to phagocytose. This anti-parasitic effect is mediated via toxic molecules released from their granules (e.g. eosinophil cationic protein and major basic protein). They also release histaminase, which limits the inflammatory consequences of mast cell degranulation. High local concentrations of eosinophils, e.g. in bronchial asthma and in cutaneous contact sensitivity and allergic eczema, can cause tissue destruction as a consequence of the release of molecules such as collagenase from their granules.

**Basophil granulocytes**

Slightly smaller than other granulocytes, basophil granulocytes are 10–14 µm in
diameter, and form only 0.5–1% of the total leukocyte population of normal blood, with a count of 25–200/µl. Their distinguishing feature is the presence of large, conspicuous basophilic granules. The nucleus is somewhat irregular or bilobed, and is usually obscured in stained blood smears by the similar colour of the basophilic granules. The granules are membrane-bound vesicles which display a variety of crystalline, lamellar and granular inclusions: they contain heparin, histamine and several other inflammatory agents, and closely resemble those of tissue mast cells (see p. 36). Both basophils and mast cells have high affinity membrane receptors for IgE and are therefore coated with IgE antibody. If this binds to its antigen it triggers degranulation of the cells, producing vasodilation, increased vascular permeability, chemotactic stimuli for other granulocytes, and the symptoms of immediate hypersensitivity, e.g. in allergic rhinitis (hay fever). Despite these similarities, basophils and mast cells develop as separate lineages in the myeloid series, from haemopoietic stem cells in the bone marrow. Evidence from experimental animal models suggests that they are closely related (see Fig. 4.12) but studies on mast cell disorders in humans indicate that their lineages diverge from a more distant ancestral progenitor (Kocabas et al 2005).

**Mononuclear leukocytes**

Monocytes

Monocytes are the largest of the leukocytes (15–20 µm in diameter), but they form only a small proportion of the total population (2–8% with a count of 100–700/µl of blood). The nucleus, which is euchromatic, is relatively large and irregular, often with a characteristic indentation on one side. The cytoplasm is pale-staining, particulate and typically vacuolated. Near the nuclear indentation it contains a prominent Golgi complex and vesicles. Monocytes are actively phagocytic cells, and contain numerous lysosomes. Phagocytosis is triggered by recognition of opsonized material, as described for neutrophils. Monocytes are highly motile, and possess a well-developed cytoskeleton.

Monocytes express Class II MHC antigens and share other similarities to tissue macrophages and dendritic cells. Most monocytes are thought to be in transit via the bloodstream from the bone marrow to the peripheral tissues where they give rise to macrophages and dendritic cells; different monocyte subsets may target inflamed tissues. Like other leukocytes, they pass into extravascular sites through the walls of capillaries and venules.

Lymphocytes

Lymphocytes (Fig. 4.4, see Fig. 4.6, see Fig. 4.12) are the second most numerous type of leukocyte in adulthood, forming 20–30% of the total population (1500–2700/µl of blood). In young children they are the most numerous blood leukocyte. Most circulating lymphocytes are small, 6–8 µm in diameter; a few are medium-sized and have an increased cytoplasmic volume, often in response to antigenic stimulation. Occasionally, cells up to 16 µm are seen in peripheral blood. Lymphocytes, like other leukocytes, are found in extravascular tissues (including lymphoid tissue); however, they are the only white blood cells which return to the circulation. The lifespan of lymphocytes ranges from a few days (short-lived) to many years (long-lived). Long-lived lymphocytes play a significant role in the maintenance of immunological memory.
Fig. 4.4 A small, resting lymphocyte in human peripheral blood. The nuclear/cytoplasmic ratio is high and the cytoplasm contains few organelles, indicative of its quiescent state.
Blood lymphocytes are a heterogeneous collection mainly of B and T cells and consist of different subsets and different stages of activity and maturity. About 85% of all circulating lymphocytes in normal blood are T cells. Primary immunodeficiency diseases can result from molecular defects in T and B lymphocytes (reviewed in Cunningham-Rundles & Ponda 2005). Included with the lymphocytes, but probably a separate lineage subset, are the natural killer (NK) cells. NK cells most closely
resemble large T cells morphologically.

Small lymphocytes (both B and T cells) contain a rounded, densely staining nucleus which is surrounded by a very narrow rim of cytoplasm, barely visible in the light microscope. In the electron microscope (Fig. 4.4), few cytoplasmic organelles can be seen apart from a small number of mitochondria, single ribosomes, sparse profiles of endoplasmic reticulum and occasional lysosomes: these features indicate a low metabolic rate and a quiescent phenotype. However, these cells become motile when they contact solid surfaces, and can pass between endothelial cells to exit from, or re-enter, the vascular system. They migrate extensively within various tissues, including epithelia (Fig. 4.5).

Fig. 4.5 Tubular glands in the appendix, showing intraepithelial lymphocytes (arrowed). A lymphocyte in anaphase is indicated (longer arrow).
Larger lymphocytes include T and B cells which are functionally activated or proliferating after stimulation by antigen, and NK cells. They contain a nucleus, which is at least in part euchromatic, a basophilic cytoplasm, which may appear granular, and numerous polyribosome clusters, consistent with active protein synthesis. The ultrastructural appearance of these cells varies according to their class and is described below.

**B cells**

B cells and the plasma cells that develop from them synthesize and secrete antibodies which can specifically recognize and neutralize foreign (non-self) macromolecules (antigens), and can prime various non-lymphocytic cells (e.g. neutrophils, macrophages and dendritic cells) to phagocytose pathogens. B cells differentiate from haemopoietic stem cells in the bone marrow. After deletion of autoreactive cells, the selected B lymphocytes then leave the bone marrow and migrate to peripheral lymphoid sites (e.g. lymph nodes). Here, following stimulation by antigen, they undergo further proliferation and selection, forming germinal centres in the lymphoid tissues. Following this, some B cells differentiate into large basophilic (RNA-rich) plasma cells, either within or outside the lymphoid tissues. Plasma cells produce antibodies in their extensive rough endoplasmic reticulum (Fig. 4.6) and secrete them into the adjacent tissues. They have a prominent pale-staining Golgi complex adjacent to an eccentrically-placed nucleus, typically with peripheral blocks of condensed heterochromatin resembling the numerals of a clock (clock-faced nucleus) (see Fig. 4.12). Other germinal centre B cells develop into long-lived memory cells capable of responding to their specific antigens not only with a more rapid and higher antibody output, but also with an increased antibody affinity compared with the primary response.

Antibodies are immunoglobulins, grouped into five classes according to their heavy polypeptide chain. Immunoglobulin G (IgG) forms the bulk of circulating antibodies. Immunoglobulin M (IgM) is normally synthesized early in immune responses. Immunoglobulin A (IgA) is present in breast milk, tears, saliva and other secretions of the alimentary tract, coupled to a secretory piece (a 70 kDa protein) which is synthesized by the epithelial cells and protects the immunoglobulin from proteolytic degradation: IgA thus contributes to mucosal immunity. IgA deficiency is relatively common, particularly in some ethnic groups (reviewed in Woof & Kerr 2006). Immunoglobulin E (IgE) is an antibody which binds to receptors on the surfaces of mast cells, eosinophils and blood basophils; it is found only at low concentrations in the circulation. Immunoglobulin D (IgD) is found together with IgM as a major membrane-bound immunoglobulin on mature, immunocompetent but naïve (prior to antigen exposure) B cells, acting as the cellular receptor for antigen.

When circulating antibodies bind to antigens they form immune complexes. If present in abnormal quantities, these may cause pathological damage to the vascular system and other tissues, either by interfering mechanically with the permeability of the basal lamina (e.g. some types of glomerulonephritis), or by causing local activation of the complement system which generates inflammatory mediators (e.g. C5a), attacks cell membranes and causes vascular disease. In pregnancy, maternal IgG crosses the placenta and confers passive immunity on the fetus. Maternal milk contains secretory immunoglobulins (IgA) which help to combat bacterial and viral organisms in the alimentary tract of the baby during the first few weeks of postnatal life.
**T cells**

There are a number of sub-sets of T (thymus-derived) lymphocytes, all progeny of haemopoietic stem cells in the bone marrow. They develop and mature in the thymus, and subsequently populate peripheral secondary lymphoid organs, which they constantly leave and re-enter via the circulation. As recirculating cells, their major function is immune surveillance. Their activation and subsequent proliferation and functional maturation is under the control of antigen-presenting cells. T cells undertake a wide variety of cell-mediated defensive functions which are not directly dependent on antibody activity, and which constitute the basis of cellular immunity. T cell responses focus on the destruction of cellular targets such as virus-infected cells, certain bacterial infections, fungi, some protozoal infections, neoplastic cells and the cells of grafts from other individuals (allografts) when the tissue antigens of the donor and recipient are not sufficiently similar. Targets may be killed directly by cytotoxic T cells, or indirectly by accessory cells (e.g. macrophages) which have been recruited and activated by cytokine-secreting helper T cells. A third group, regulatory T cells, acts to regulate or limit immune responses.

Functional groups of T cells are classified according to the molecules they express on their surfaces. The majority of cytokine-secreting helper T cells express CD4, while cytotoxic T cells are characterized by CD8. Regulatory T cells coexpress CD4 and CD25. The CD (cluster of differentiation) prefix provides a standard nomenclature for all cell surface molecules. At present, more than 330 different CD antigens have been designated: each one represents a cell surface molecule that can be identified by specific antibodies. Further details of the classification are beyond the scope of this publication and are given in Male et al (2006).

Structurally, T lymphocytes present different appearances depending on their type and state of activity. When resting, they are typical small lymphocytes and are morphologically indistinguishable from B lymphocytes. When stimulated, they become large (up to 15 µm), moderately basophilic cells, with a partially euchromatic nucleus and numerous free ribosomes, rough and smooth endoplasmic reticulum, a Golgi complex and a few mitochondria, in their cytoplasm. Cytotoxic T cells contain dense lysosome-like vacuoles which function in cytotoxic killing.

**Cytotoxic T cells**

Cytotoxic T lymphocytes (which express CD8 on their surface) are responsible for the direct cytotoxic killing of target cells (e.g. virus-infected cells): the requirement for direct cell–cell contact ensures the specificity of the response. Recognition of antigen, presented as a peptide fragment on MHC class I molecules, triggers the calcium-dependent release of lytic granules by the T cell. These lysosome-like granules contain perforin which forms a pore in the target cell membrane. They also contain several different serine protease enzymes (granzymes) which enter the target cell via the perforin pore and induce the programmed cell death (apoptosis; p. 24) of the target.

**Helper T cells**

Helper T cells (which express CD4) are characterized by the secretion of cytokines. Two major populations have been identified according to the range of cytokines produced. Th1 helper T cells typically secrete interleukin (IL)-2, tumour necrosis factor...
(TNF)-alpha and interferon gamma, while Th2 cells produce cytokines such as IL-4, IL-5 and IL-13. These two CD4-expressing populations are termed ‘helper’ T cells because one aspect of their function is to stimulate the proliferation and maturation of B lymphocytes and cytotoxic T lymphocytes (mediated via cytokines such as IL-4, IL-2 and interferon gamma), thus enabling and enhancing the immune responses mediated by those cells. In addition to Th1 and Th2 cells, other subsets of helper T cells have been described. Notably, Th17 cells (which secrete the cytokine IL-17) have recently been implicated in autoimmune diseases.

However, helper T cells are also important in directing the destruction of pathogens by recruiting accessory cells (e.g. macrophages, neutrophils, eosinophils) to the site of infection and by activating their effector functions. This process is tightly coordinated. For example, Th1 helper T cells secrete cytokines that not only attract and activate macrophages but also provide help for B cells and guide their immunoglobulin production to the subclasses that fix complement. Thus these antibodies opsonize the pathogen target which can then be recognized, ingested and destroyed by the macrophage accessory cells that bear receptors for complement and the Fc region of IgG. These Th1 cells are sometimes referred to as delayed type hypersensitivity T cells. In contrast, Th2 cells secrete cytokines that induce the development and activation of eosinophils, and also induce B cells to switch their immunoglobulins to non-complement fixing classes (e.g. IgE). Pathogens such as parasitic worms can then be coated with IgE antibody and hence recognized and destroyed by the effector functions of the eosinophil accessory cells which bear receptors for the Fc region of IgE.

If helper T-cell activities are non-functional, a state of immunodeficiency results. This means that potentially pathogenic organisms, which are normally kept in check by the immune system, may proliferate and cause overt pathology, e.g. in acquired immune deficiency syndrome (AIDS), where a virus (HIV) specifically infects and kills (predominantly) helper T cells, though some antigen-presenting cells are also killed.

**Regulatory T cells**

A third population of T cells, ‘regulatory’ T or ‘Treg’ cells has been identified within the last decade (reviewed in O’Garra & Vieira 2004). These CD4+, CD25+ cells have an immunomodulatory function and can dampen the effector functions of both cytotoxic and helper T cells. Regulatory T cells are produced in the thymus and are an important additional mechanism for maintaining self-tolerance. Treg function is antigen-specific and depends upon direct cell–cell contact. Molecules secreted or induced by Treg cells, such as interleukin (IL)-10 or transforming growth factor (TGF) β, may also play an important role in mediating Treg suppressive effects on the immune system. Similar regulatory T cells can be induced in the periphery and may be important in the induction of oral tolerance to ingested antigens as well as tolerance to tissue specific molecules that are not expressed in the thymus.

**Natural killer (NK) cells**

Natural killer (NK) cells have functional similarities to cytotoxic T cells. However they lack other typical lymphocyte features, and do not express antigen-specific receptors. They normally form only a small percentage of all lymphocyte-like cells and are usually included in the large granular lymphocyte category. When mature, NK cells
have a mildly basophilic cytoplasm. Ultrastructurally, their cytoplasm contains ribosomes, rough endoplasmic reticulum and dense, membrane-bound vesicles 200–500 nm in diameter with crystalline cores. These contain the protein perforin (cytolysin), which is capable of inserting holes in the plasma membranes of target cells, and granzymes (serine proteases), which trigger subsequent target cell death by apoptosis. NK cells are activated to kill target cells by a number of factors. They can recognize and kill antibody coated target cells via a mechanism termed antibody-dependent cell-mediated cytotoxicity (ADCC). They also have receptors that inhibit NK destructive activity when they recognize MHC class I on normal cells. When NK cells detect the loss or downregulation of MHC class I antigens on certain virus-infected cells and some tumour cells, they activate apoptosis-inducing mechanisms which enable them to attack these abnormal cells, albeit relatively non-specifically. For further reading, see Vivier et al 2008.

**Platelets**

Blood platelets, also known as thrombocytes, are relatively small (2–4 µm across) irregular or oval discs present in large numbers (200,000–400,000/µl) in blood. In freshly harvested blood samples they readily adhere to each other and to all available surfaces, unless the blood is treated with citrate or other substances which reduce the availability of calcium ions. Platelets are anucleate cell fragments, derived from megakaryocytes in the bone marrow. They are surrounded by a plasma membrane with a thick glycoprotein coat, which is responsible for their adhesive properties. A band of 10 microtubules lies around the perimeter of the platelet beneath the plasma membrane: the microtubules are associated with actin filaments, myosin and other proteins related to cell contraction. The cytoplasm also contains mitochondria, glycogen, scant smooth endoplasmic reticulum, tubular invaginations of the plasma membrane, and three major types of membrane-bound vesicle, designated alpha, delta and lambda granules.

Alpha granules are the largest, and have diameters of up to 500 nm. They contain platelet-derived growth factor (PDGF), fibrinogen and other substances. Delta granules are smaller (up to 300 nm), and contain 5-hydroxytryptamine (serotonin) which has been endocytosed from the blood plasma. Lambda granules are the smallest (up to 250 nm) and contain lysosomal enzymes.

Platelets play an important role in haemostasis. When a blood vessel is damaged, platelets become activated, evert their membrane invaginations to form lamellipodia and filopodia, and aggregate at the site of injury, plugging the wound. They adhere to each other (agglutination), and to other tissues. Adhesion is a function of the thick platelet coat and is promoted by the release of ADP and calcium ions from the platelets in response to vessel injury. The contents of released alpha granules, together with factors released from the damaged tissues, initiate a complex sequence of chemical reactions in the blood plasma, which leads to the precipitation of insoluble fibrin filaments in a three-dimensional meshwork, the fibrin clot (Fig. 4.1). More platelets attach to the clot, inserting extensions of their surfaces, filopodia, deep into the spaces between the fibrin filaments, to which they adhere strongly. The platelets then contract (clot retraction) by actin–myosin interactions within their cytoplasm, and this concentrates the fibrin clot and pulls the walls of the blood vessel together, which limits any further leakage of blood. After repair of the vessel wall, which may be promoted by the mitogenic activity of PDGF, the clot is dissolved by enzymes such as
plasmin. Plasmin is formed by plasminogen activators in the plasma, probably assisted by lysosomal enzymes derived from the lambda granules of platelets. Platelets typically circulate for 10 days before they are removed, mainly by splenic macrophages.
LYMPHOID TISSUES

Lymphocytes are located in many sites in the body, most obviously at strategic sites which are liable to infection, e.g. the oropharynx. The main areas of lymphocyte concentration are classified as primary or secondary lymphoid organs, according to whether they are involved in de novo lymphocyte generation (primary lymphoid organs, e.g. bone marrow, thymus) or the site of mature lymphocyte activation and initiation of an immune response (secondary lymphoid organs, e.g. lymph nodes, spleen).

All lymphocytes arise from pluripotent haemopoietic stem cells in the bone marrow. The B lymphocyte lineage develops through a series of differentiation stages within the bone marrow. The newly formed B cells then leave through the circulation and migrate to peripheral sites. In contrast, T lymphocyte development requires the thymus; the bone marrow-derived stem cells must therefore migrate via the blood circulation to the thymus. After their differentiation and maturation into immunocompetent T cells which have survived thymic selection processes (1–3%), they re-enter the circulation and are transported to peripheral sites where they join the pool of naive lymphocytes which recirculate through the secondary lymphoid organs via blood and lymphatic circulation systems.

The secondary or peripheral lymphoid organs are the specialized sites where B and T lymphocytes and antigen presenting cells come together to initiate immune responses to foreign antigens. These secondary tissues include lymph nodes, spleen, and lymphoid tissue associated with epithelial surfaces (mucosa-associated lymphoid tissue, MALT), e.g. the palatine and nasopharyngeal tonsils, Peyer's patches in the small intestine, lymphoid nodules in the respiratory and urogenital systems, the skin and conjunctiva of the eye. The microstructure of lymph nodes and of general MALT are described below. Details of all other lymphoid tissues and organs are included in the descriptions of the appropriate regional anatomy.

Lymphocytes enter secondary lymphoid tissues from the blood, usually by migration through the walls of capillaries or venules (high endothelial venules, HEV) and leave by the lymphatic system. In the spleen, lymphocyte entry and exit is via the marginal zone and venous drainage respectively. Antigen presenting cells (dendritic cells) enter via the lymphatics, bringing with them antigen from peripheral infected sites. In all the secondary tissues there are specific areas where either B or T cells are concentrated. After activation, functionally competent lymphocytes migrate to other sites in the body, where they combat the original infection.

LYMPH NODES

Lymph nodes (Fig. 4.7) are encapsulated centres of antigen presentation and lymphocyte activation, differentiation and proliferation. They generate mature, antigen-primed, B and T cells, and filter particles, including microbes, from the lymph by the action of numerous phagocytic macrophages. A normal young adult body contains up to 450 lymph nodes, of which 60–70 are found in the head and neck, 100 in the thorax and as many as 250 in the abdomen and pelvis. Lymph nodes are particularly numerous in the neck, mediastinum, posterior abdominal wall, abdominal mesenteries, pelvis and proximal regions of the limbs (axillary and inguinal lymph nodes). By far the greatest number lie close to the viscera, especially in the
mesenteries.

**Microstructure**

Lymph nodes (Fig. 4.8) are small, oval or kidney-shaped bodies, 0.1–2.5 cm long, lying along the course of the lymphatic vessels. Each usually has a slight indentation on one side, the hilum, through which blood vessels enter and leave and the efferent lymphatic vessel leaves. Several afferent lymphatic vessels enter the capsule around the periphery. Lymph nodes have a highly cellular cortex and a medulla which contains a network of minute lymphatic channels (sinuses) through which lymph from the afferent lymphatics is filtered, to be collected at the hilum by the efferent lymphatic. The cortex is absent at the hilum, where the medulla reaches the surface.
The capsule is composed mainly of collagen fibres, elastin fibres (especially in the deeper layers), and a few fibroblasts. From the capsule, trabeculae of dense connective tissue extend radially into the interior of the node. They are continuous with a network of fine type III collagen (reticulin) fibrils which supports the lymphoid tissue. At the hilum, dense fibrous tissue may extend into the medulla, surrounding the efferent lymphatic vessel.

The fine reticulin bundles branch and interconnect to form a very dense network in the cortex: there are fewer fibres in the germinal centres of follicles (see below). They provide attachment for various cells, mostly dendritic cells, macrophages and lymphocytes. Reticulin and the associated proteoglycan matrix are produced by fibroblasts, a few of which are associated with the fibre network.

**Lymphatic and vascular supply**

Lymph nodes are permeated by channels through which lymph percolates after its entry from the afferent vessels. Macrophages line the channels or migrate along the reticulin which crosses them, and so lymph is exposed to their phagocytic activities, as well as to B and T lymphocytes which lie within the various regions of a node. Afferent lymphatic vessels enter at many points on the periphery, branch to form a dense intracapsular plexus, and then open into the subcapsular sinus, a cavity which is peripheral to the whole cortex except at the hilum (Fig. 4.7). Numerous radial cortical sinuses lead from the subcapsular sinus to the medulla, where they coalesce as larger medullary sinuses. The latter become confluent at the hilum with the efferent vessel which drains the node. All of these spaces are lined by a continuous endothelium and traversed by fine reticular fibres, which support sinus macrophages.

Arteries and veins serving lymph nodes pass through the hilum, giving off straight branches which traverse the medulla, and sending out minor branches as they do so. In the cortex, arteries form dense arcades of arterioles and capillaries in numerous anastomosing loops, eventually returning to highly branched venules and veins.
Capillaries are especially profuse around the follicles, which contain fewer vessels. Postcapillary HEV are abundant in the paracortical zones. They form an important site of blood-borne lymphocyte extravasation into lymphoid tissue, apparently by migration through labile endothelial tight junctions. The density of the capillary beds increases greatly when lymphocytes multiply in response to antigenic stimulation. Veins leave a node through its principal trabeculae and capsule, and drain them and the surrounding connective tissue.

**Cells and cellular zones of lymph nodes**

Although most of the cells in a lymph node are B and T lymphocytes, their distribution is not homogeneous. In the cortex, cells are densely packed and in the outer cortical area they form lymphoid follicles or nodules (Fig. 4.8), which are populated mainly by B cells and specialized follicular dendritic cells (FDC) (see Fig. 4.15). The number, degree of isolation and staining characteristics of follicles vary according to their state of antigenic stimulation. A primary follicle is uniformly populated by small, quiescent lymphocytes, whereas a secondary follicle has a germinal centre (Fig. 4.9) which is composed mainly of antigen-stimulated B cells which are larger, less deeply staining and more rapidly dividing than those at its periphery.

![Fig. 4.15](image)

*Fig. 4.15* Follicular dendritic cells (brown) in a germinal centre of the human palatine tonsil (immunoperoxidase labelled). *(By courtesy of Dr Marta Perry, UMDS, London.)*
The role of the germinal centre is to provide a microenvironment which allows the affinity maturation of the B cell response, so that as the immune response progresses...
the affinity or strength with which antibodies bind their antigen also increases. There are several zones in the germinal centre where this is allowed to happen. In the 'dark zone' the B cells (centroblasts) undergo rapid proliferation which is associated with hypermutation of their antibody molecules. They then move into the light zone (as centrocytes), where they can interact with the FDCs which carry intact unprocessed antigen on their surface. The centrocytes compete for binding to the antigen; those whose antibody has the highest affinity survive and the rest die. T cells are also present, helping the survival of the B cells and inducing class switching. Macrophages in the germinal centre phagocytose apoptotic lymphocytes (e.g. those B cells which die as part of the process of affinity maturation), and consequently macrophage cytoplasm becomes filled with engulfed lipid and nuclear debris.

The mantle zone (Fig. 4.9) is produced as surrounding cells are marginalized by the rapidly growing germinal centre. It is populated by cells similar to those found in primary follicles, mainly quiescent B cells with condensed heterochromatic nuclei and little cytoplasm (hence the deeply basophilic staining of this region in routine preparations; Fig. 4.10), a few helper T cells, FDCs and macrophages. After numerous mitotic divisions the selected B cells give rise to small lymphocytes, some of which become memory B cells and leave the lymph node to join the recirculating pool, while others leave to mature as antibody-secreting plasma cells either in the lymph node medulla or in peripheral tissues.
The deep cortex or paracortex lies between the cortical follicles and the medulla, and is populated mainly by T cells, which are not organized into follicles. Both CD4 and CD8 T cell subsets are present. The paracortex also contains interdigitating dendritic cells. These dendritic cells include Langerhans cells from the skin and other squamous epithelia which have migrated as veiled cells via the afferent lymphatics into the draining lymph nodes (see Fig. 4.14). Their role is to present processed antigen to T cells. The region expands greatly in T cell-dominated immune responses, when its cells are stimulated to proliferate and disperse to peripheral sites.
In the medulla, lymphocytes are much less densely packed, forming irregular, branching medullary cords between which the reticulin network is easily seen. Other cells include macrophages, which are more numerous in the medulla than in the cortex, plasma cells and a few granulocytes.
MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT)

Large amounts of unencapsulated lymphoid tissue exist in the walls of the alimentary, respiratory, reproductive and urinary tracts, and in the skin: they are collectively termed mucosa-associated lymphoid tissue (MALT). Some authorities distinguish between lymphoid tissues associated with different organ systems of the body. Although there may be functional differences between them related to the different antigenic challenges encountered, this is not evident in their microstructure. Anatomically, the main subclasses are gut-associated lymphoid tissue (GALT) and bronchus-associated lymphoid tissue (BALT).

Throughout the body, MALT includes an extremely large population of lymphocytes, principally because of the size of the alimentary tract. The lymphoid cells are located in the lamina propria and in the submucosa as discrete follicles or nodules. More scattered cells, derived from these follicles, are found throughout the lamina propria and in the base of the epithelium (Fig. 4.5, Fig. 4.10). MALT includes macroscopically visible lymphoid masses, notably the peripharyngeal lymphoid (Waldeyer's) ring of tonsillar tissue (palatine, nasopharyngeal, tubal and lingual), and the Peyer's patches of the small intestine (see Ch. 66) which are described elsewhere. Most MALT consists of microscopic aggregates of lymphoid tissue, and lacks a fibrous capsule. Lymphocyte populations are supported mechanically by a fine network of fine type III collagen (reticulin) fibres and associated fibroblasts, as they are in lymph nodes.

In common with lymph nodes, MALT provides centres for the activation and proliferation of B and T lymphocytes in its follicles and parafollicular zones, respectively. The function of cells in these zones, including antigen presenting cells (follicular dendritic cells and interdigitating dendritic cells) and macrophages as well as T and B cells, is similar to that found in lymph nodes. The close proximity of lymphocytes within the MALT to an epithelial surface facilitates their access to pathogens. The lymphocyte population in MALT is not fixed: lymphocytes migrate into MALT through its HEV and leave mainly via its efferent lymphatics, which drain interstitial fluid as lymph. MALT lacks afferent lymphatic vessels. Migration from MALT follows a different route from the major peripheral route of recirculation. After antigen activation, lymphocytes travel via the regional lymph nodes to disperse widely along mucosal surfaces to provide protective T- and B-cell immunity.

Follicle-associated epithelium

The epithelium covering mucosa-associated lymphoid tissue, which varies in type according to its location, is unusual in possessing cells which are involved in sampling antigens and passing them to the underlying tissues. The main function of B lymphocytes in MALT is to produce IgA for secretion
into the lumen of the tracts which they line. They are exposed to antigens present in the lumen because the epithelium samples and transfers these antigens to antigen-presenting cells in the underlying tissues. Appropriate clones of T and B cells in local lymphoid tissues are then activated and amplified prior to their exit via the lymphatics. In the small and large intestine these specialized epithelial cells have characteristic short microvilli on their luminal surface and are known as microfold (M) cells. In the palatine tonsils they include modified stratified squamous reticulated epithelial cells.

Thus, many of the lymphocytes migrating between cells in the basal regions of epithelia (Fig. 4.5) are effector cytotoxic and helper T cells that have already been selected in lymphoid nodules and are engaged in immune responses. Similar cells, and activated IgA-producing B cells and plasma cells, are also scattered throughout the entire mucosal lamina propria.
HAEMOPOIESIS

Postnatally, blood cells are formed primarily in the bone marrow. Other tissues, particularly the spleen and liver, may develop haemopoietic activity once more, if production from the marrow is inadequate.

BONE MARROW

Bone marrow is a soft pulpy tissue which is found in the marrow cavities of all bones (Fig. 4.11) and even in the larger Haversian canals of lamellar bone. It differs in composition in different bones and at different ages and occurs in two forms, yellow and red marrow. In old age the marrow of the cranial bones undergoes degeneration and is then termed gelatinous marrow.
Yellow marrow

Yellow marrow consists of a framework of connective tissue which supports numerous blood vessels and cells, most of which are adipocytes. A small population of typical red marrow cells persists and may be reactivated when the demand for blood cells becomes sufficiently great.

Red marrow

Red marrow is found throughout the skeleton in the fetus and during the first years of life. After about the fifth year the red marrow, which represents actively haemopoietic tissue, is gradually replaced in the long bones by yellow marrow. The replacement starts earlier, and is generally more advanced, in the more distal bones. By 20–25 years of age, red marrow persists only in the vertebrae, sternum, ribs, clavicles, scapulae, pelvis, cranial bones and in the proximal ends of the femur and humerus.

Red bone marrow consists of a network of loose connective tissue, the stroma, which
supports clusters of haemopoietic cells (haemopoietic cords or islands) and a rich vascular supply in which large, thin-walled sinusoids are the main feature (Fig. 4.11). The vascular supply is derived from the nutrient artery to the bone, which ramifies in the bone marrow, and terminates in thin-walled arterioles from which the sinusoids arise. These, in turn, drain into disproportionately large veins. Lymphatic vessels are absent from bone marrow. The stroma contains a variable amount of fat, depending on age, site and the haematological status of the body, and small patches of lymphoid tissue are also present. Marrow thus consists of vascular and extravascular compartments, both enclosed within a bony framework from which they are separated by a thin layer of endosteal cells (p. 91).

**Stroma**

Stroma is composed of a delicate network of fine type III collagen (reticulin) fibres secreted by highly branched, specialized fibroblast-like cells (reticular cells) derived from embryonic mesenchyme. When haemopoiesis stops, as occurs in most limb bones in adult life, these cells (or closely related cells) become distended with lipid droplets, and fill the marrow with yellow fatty tissue (yellow marrow). If there is a later demand for haemopoiesis, the stellate stromal cells reappear. The stroma also contains numerous macrophages attached to extracellular matrix fibres. These cells actively phagocytose cellular debris created by haemopoietic development, especially the extruded nuclei of erythroblasts, remnants of megakaryocytes and cells which have failed the B lymphocyte selection process. Stromal cells play a major role in the control of haemopoietic cell differentiation, proliferation and maturation.

Marrow sinusoids are lined by a single layer of endothelial cells, supported by reticulin on their basal surfaces. Although the endothelial cells are interconnected by tight junctions, their cytoplasm is extremely thin in places, and the underlying basal lamina is discontinuous. The passage of newly formed blood cells from the haemopoietic compartment into the bloodstream appears to occur through an interactive process with the endothelium, producing temporary apertures (large fenestrae) in their attenuated cytoplasm.

**Haemopoietic tissue**

Cords and islands of haematogenous cells consist of clusters of immature blood cells in various stages of development; several different cell lineages are typically represented in each focal group. One or more macrophages lie at the core of each such group of cells. These macrophages engage in phagocytic functions, are important in transferring iron to developing erythroblasts for haemoglobin synthesis, and may play a role, with other stromal cells, in regulating the rate of cell proliferation and maturation of the neighbouring haemopoietic cells.
**CELL LINEAGES**

**Haemopoietic stem cells**

Within the adult marrow there is a very small number (0.05% of haemopoietic cells) of self-renewing, pluripotent stem cells which are capable of giving rise to all blood cell types, including lymphocytes (Fig. 4.12). Although they cannot be identified morphologically in the marrow, they can be recognized in aspirates by the expression of specific cell surface marker proteins (e.g. CD34). It is thought that haemopoietic stem cells occupy specific environmental niches in the marrow associated with the endosteum of trabecular bone or with sinusoidal endothelium and that their microenvironment is important in homeostasis, the balance between self-renewal and differentiation. Stem cells can also be found (at lower concentrations) in the peripheral blood, particularly after treatment with appropriate cytokines.

Progressively more lineage-restricted committed progenitor cells develop from these ancestors (see Laiosa et al 2006 for a recent review) to produce the various cell types found in peripheral blood. The committed progenitor cells are often termed colony-forming units (CFU) of the lineage(s), e.g. CFU-GM cells give rise, after proliferation, to neutrophil granulocytes, monocytes and certain dendritic cells, whereas CFU-E produce only erythrocytes. Each cell type undergoes a period of maturation in the marrow, often accompanied by several structural changes, before release into the general circulation. In some lineages, e.g. the erythroid series, the final stages of maturation take place in the circulation, whereas in the monocytic lineage, they occur after the cells have left the circulation and entered peripheral tissues where they differentiate into macrophages and some dendritic cells.

To generate a complete set of blood cells from a single pluripotent cell may take some months. The later progenitor cells form mature cells of their particular lineages more quickly. However, because they are not self-renewing, grafts of these later cells eventually fail because the cells they produce all ultimately die. This is of considerable importance in bone marrow replacement therapy. The presence of pluripotent stem cells in the donor marrow is essential for success: only 5% of the normal number are needed to repopulate the marrow. Following replacement therapy, T lymphocytes reconstitute more slowly than the other haemopoietic lineages, reflecting the progressive reduction in size of the thymus with age (chronic involution).

**Lymphocytes**

Lymphocytes are a heterogeneous group of cells which may share a common ancestral lymphoid progenitor cell, distinct from the myeloid progenitor cell which gives rise to all of the cell types described above. The
first identifiable progenitor cell is the lymphoblast, which divides several times to form prolymphocytes: both cells are characterized by a high nuclear to cytoplasmic ratio. B cells undergo differentiation to their specific lineage subset entirely within the bone marrow and migrate to peripheral or secondary lymphoid tissues as naïve B cells, ready to respond to antigen. However, T cells require the specialized thymic microenvironment for their development. During fetal and early postnatal life, and subsequently at lower levels throughout life, progenitor cells migrate to the thymus where they undergo a process of differentiation and selection as T cells, before leaving to populate secondary lymphoid tissues.

B cell development

B cells start their development in the subosteal region of the bone marrow, and move centripetally as differentiation progresses. Their development entails the rearrangement of immunoglobulin genes to create a unique receptor for antigen on each B cell, and the progressive expression of cell surface and intracellular molecules required for mature B lymphocyte function. Autoreactive cells which meet their self-antigen within the bone marrow are eliminated. Overall some 25% of B cells successfully complete these developmental and selection processes: those that fail die by apoptosis and are removed by macrophages. Bone marrow stromal cells (fibroblasts, fat cells and macrophages) express cell surface molecules and secreted cytokines which control B lymphocyte development. The mature naïve B lymphocytes leave via the central sinuses. They express antigen receptors (immunoglobulin) of IgM and IgD classes. Class switching to IgG, A and E occurs in the periphery following antigen activation in response to signals from T helper cells.

T-cell (thymocyte) development

T cells develop within the thymus from blood-borne bone marrow-derived progenitors which enter the thymus via HEVs at the corticomedullary junction. They first migrate to the outer (subcapsular) region of the thymic cortex and then, as in the bone marrow, move progressively inwards towards the medulla as development continues. T-cell development involves gene rearrangements in the T-cell receptor (TcR) loci to create unique receptors for antigen on each cell, together with the progressive expression of molecules required for mature T-cell function. Selection of the receptor repertoire is more stringent for T cells than for B cells because of the way in which mature T cells recognize cell-bound antigens presented in conjunction with specific proteins of the major histocompatibility complex (MHC) expressed on the surfaces of cells. Thus mature CD8 (cytotoxic) T cells recognize antigen in the form of short peptides complexed with the polymorphic MHC class I molecules, while CD4 (helper/regulatory) T cells recognize the peptides in the context of MHC class II molecules. Because the
TcR recognizes both the peptide and the MHC molecule, the T cell will only recognize peptides bound to their own (self) type of MHC: they will not 'see' peptides in combination with allelically different MHC molecules (i.e. those from other individuals). This is termed MHC restriction of T-cell recognition. Selection of T cells in the thymus must ensure the survival of those T cells which can respond only to foreign antigens, bound to their own (self) class of MHC molecule. Cells which are incapable of binding to self MHC molecules, or which bind to self-antigens, are eliminated by apoptotic cell death: it is estimated that up to 95% of T cell progenitors undergo apoptosis in this way. Cells which express an appropriate TcR and have effective MHC-restricted binding properties survive to become mature, naïve T cells which leave the thymus and populate the periphery.

Thymic stromal cells play a crucial role in T-cell development and selection. Thymic epithelial cells in the cortex express both MHC class I and II molecules and are unique in their ability to select T cells which recognize self MHC (positive selection). Deletion of self-antigen reactive cells (negative selection) is mainly controlled by thymic dendritic cells located at the corticomedullary junction and in the medulla, although the epithelium can also perform this function. Apoptotic thymocytes are removed by thymic macrophages. The role of the thymic epithelium in thymocyte differentiation is complex and involves cell–cell contact as well as the secretion of soluble mediators such as cytokines, chemokines, neuroactive peptides (e.g. somatostatin) and thymic hormones (e.g. thymulin). Thymic fibroblasts and the extracellular matrix also play a role.

**Erythrocytes**

Erythrocytes and granulocytes belong to the myeloid lineage. The earliest identifiable erythroid progenitor cells are capable of rapid bursts of cell division to form numerous daughter cells; they have thus been named burst-forming units of the erythroid line (BFU-E). They give rise to the CFU-E, which, with their immediate progeny, are sensitive to the hormone erythropoietin. This hormone, produced in the kidney, induces further differentiation along the erythroid line.

The first readily identifiable cell of the erythroid series is the proerythroblast, which is a large (about 20 µm) cell with a large euchromatic nucleus and a moderately basophilic cytoplasm. It also responds to erythropoietin. The proerythroblast contains small amounts of ferritin and bears some of the protein spectrin on its plasma membrane. Proerythroblasts proliferate to produce smaller (12–16 µm) basophilic erythroblasts, rich in ribosomes, in which haemoglobin-RNA synthesis begins. The cytoplasm becomes partially, and then uniformly, eosinophilic (the polychromatic erythroblast and orthochromatic erythroblast respectively). These cells are only 8–10 µm in diameter and contain very little cytoplasmic RNA. The nucleus becomes
pyknotic (dense, deep-staining, shrunken) and is finally extruded from the cell, leaving an anucleate reticulocyte, which enters a sinusoid. Its reticular staining pattern, visible using special stains, results from residual cytoplasmic RNA which is usually lost within 24 hours of entering the peripheral blood circulation. Reticulocyte numbers in peripheral blood are therefore a good indicator of the rate of red cell production. The whole process of erythropoiesis takes 5–9 days.

**Granulocytes**

Granulocyte formation involves major changes in nuclear morphology and cytoplasmic contents which are best known for the neutrophil. Initially, myeloid progenitor cells transform into large (10–20 µm) myeloblasts which are similar in general size and appearance to proerythroblasts. These proliferative cells have large euchromatic nuclei and lack cytoplasmic granules. They differentiate into slightly larger promyelocytes, in which the first group of specific proteins is synthesized in the rough endoplasmic reticulum and Golgi apparatus. The proteins are stored in large (0.3 µm) primary (non-specific) granules, which are large lysosomes containing acid phosphatase. Smaller secondary (specific) granules are formed in the smaller myelocyte, which is the last proliferative stage. The nucleus is typically flattened or slightly indented on one side in myelocytes.

In the next, metamyelocyte, stage, the cell size (10–15 µm) decreases, the nucleus becomes heterochromatic and horse-shoe shaped, and protein synthesis almost stops. As the neutrophil is released, the nucleus becomes first heavily indented (the juvenile stab or band form), and subsequently segmented into up to six lobes, characteristic of the mature neutrophil. The whole process usually takes 7 days to complete, of which 3 days are spent proliferating, and 4 days maturing. Neutrophils may then be stored in the marrow for a further 4 days, depending on demand, before their final release into the circulation.

Eosinophils and basophils pass through a similar sequence but their nuclei do not become as irregular as that of the neutrophil. It is thought that these cells each arise from distinct colony-forming units, which are separate from the CFU-GM.

**Monocytes**

Monocytes are formed in the bone marrow. Monocytes and neutrophils appear to be closely related cells: together with some of the antigen-presenting dendritic cells, they arise from a shared progenitor, the colony-forming unit for granulocytes and macrophages (CFU-GM). Different colony-stimulating factors (CSF) act on the common progenitor to direct its subsequent differentiation pathway. Monocyte progenitors pass through a
proliferative monoblast stage (14 µm) and then form differentiating promonocytes, which are slightly smaller cells in which production of small lysosomes begins. After further divisions, monocytes (up to 20 µm) are released into the general circulation. Most migrate into perivascular and extravascular sites, which they then populate as macrophages, while others may give rise to certain dendritic cells, including Langerhans cells.

**Platelets**

Platelets arise in a unique manner by the shedding of thousands of cytoplasmic fragments from the tips of processes of megakaryocytes in the bone marrow. The first detectable cell of this line is the highly basophilic megakaryoblast (15–50 µm), followed by a promegakaryocyte stage (20–80 µm), in which synthesis of granules begins. Finally, the fully differentiated megakaryocyte, a giant cell (35–160 µm) with a large, dense, polyploid, multilobed nucleus, appears. Once differentiation is initiated from the CFU-Meg, DNA replicates without cytoplasmic division (endoreduplication), and the chromosomes are retained within a single polyploid nucleus which may contain up to 256n chromosomes (where n is the haploid complement present in gametes). Megakaryocyte lineage characteristics and disorders are reviewed in Sun et al (2006).

The cytoplasm contains fine basophilic granules and becomes partitioned into proplatelets by invaginations of the plasma membrane. These are seen ultrastructurally as a network of tubular profiles which coalesce to form cytoplasmic islands 3–4 µm in diameter. Individual platelets are shed into the circulation from a long, narrow process of megakaryocyte cytoplasm which is protruded through an aperture in the sinusoidal endothelium.
PHAGOCYTES AND ANTIGEN-PRESENTING CELLS

Macrophages and neutrophils (see above) are specialized phagocytes. Certain dendritic cells (see Fig. 4.12), e.g. Langerhans cells of the skin and other stratified squamous epithelia, are ‘professional’ antigen-presenting cells (APCs): they take up foreign material by endocytosis and macropinocytosis, and are uniquely capable of efficiently activating naïve as well as mature T lymphocytes. Macrophages are also able to process and present antigen to lymphocytes, but are less effective than dendritic cells. In addition they play an important role in the effector arm of the immune response, clearing the infectious agent by phagocytosis. The third major cell type involved in antigen presentation and T cell activation is the B lymphocyte, which is particularly efficient at taking up antigen that binds to its surface immunoglobulin (see above). Follicular dendritic cells of lymph nodes, MALT and the spleen are capable of presenting non-processed antigen to B lymphocytes, but are not classic APCs because they cannot present antigen to helper T cells.

APCs endocytose antigen, digest it intracellularly, mostly to peptide fragments, and present the fragments on their surfaces, generally in conjunction with MHC class II molecules. (Class II molecules are normally found only on APCs, although many other cells can express class II molecules in inflammatory situations.) Recognition of foreign antigen is controlled by a variety of APC cell surface receptors: Fc and complement receptors mediate uptake of opsonized material, while pattern recognition receptors of the innate immune system, e.g. Toll-like receptors and scavenger receptors, directly recognize pathogen-derived molecules.

MACROPHAGES

The mononuclear phagocyte system consists of the blood monocytes, from which the other types are derived, and various tissue macrophages, some of which have tissue-specific names. Certain dendritic cells are sometimes included in the mononuclear phagocyte system: although they share a common lineage ancestor, they appear to form a discrete branch of the family tree. Most monocytes and macrophages express class II MHC molecules.

Macrophages are very variable in size (generally 15–25 µm) and are found in many tissues of the body, where they constitute a heterogeneous family of cells (reviewed in Gordon & Taylor 2005). They are migrant cells in all general connective tissues, the alveolar macrophages in the lung, Kupffer cells in liver sinusoids, in bone marrow and in all lymphoid tissues. Macrophages often aggregate in subserous connective tissue of the pleura and peritoneum, where they are visible as milky spots near small lymphatic trunks. They cluster around the terminations of small (penicillar) arterioles in the spleen and are distributed, more diffusely, throughout the splenic cords.

Osteoclasts (up to 100 µm) in bone are closely related to macrophages. However they are syncytial cells derived from the fusion of up to 30 progenitor monocytes in bone tissue, where they differentiate further. Microglia of the central nervous system (CNS) are thought to be monocytic in origin: they migrate into the CNS during its development. They differ from macrophages in that normally they are quiescent cells in which MHC class II expression is downregulated, and they display little phagocytic activity.
Macrophages vary in structure depending on their location in the body. All have a moderately basophilic cytoplasm containing some rough and smooth endoplasmic reticulum, an active Golgi complex and a large, euchromatic and somewhat irregular nucleus. These features are consistent with an active metabolism: synthesis of lysosomal enzymes continues in mature cells. All macrophages have irregular surfaces with protruding filopodia and they contain varying numbers of endocytic vesicles, larger vacuoles and lysosomes. Some macrophages are highly motile, whereas others tend to remain attached and sedentary, e.g. in hepatic and lymphoid sinuses. Within connective tissues, macrophages may fuse to form large syncytia (giant cells) around particles which are too large to be phagocyted, or when stimulated by the presence of infectious organisms, e.g. *Mycobacterium tuberculosis*.

When blood-borne monocytes enter the tissues through the endothelial walls of capillaries and venules, they can undergo a limited number of rounds of mitosis as tissue macrophages before they die and are replaced from the bone marrow, typically after several weeks. There is some evidence that alveolar macrophages of the lung are able to undergo many more mitoses than other macrophages.

**Phagocytosis**

The uptake of particulate material and microorganisms is carried out by macrophages in many tissues and organs. When present in general connective tissue, they ingest and kill invading microorganisms and remove debris that has been produced as a consequence of tissue damage. They recognize, engulf and rapidly ingest apoptotic cells in all situations: the mechanism of apoptotic cell uptake does not activate the phagocyte for antigen presentation, and so the process is immunologically silent. In the lung, alveolar macrophages constantly patrol the respiratory surfaces, to which they migrate from pulmonary connective tissue (Fig. 4.13). They engulf inhaled particles including bacteria, surfactant and debris and many enter the sputum (hence their alternative names, dust cells or, in cardiac disease, heart failure cells, which are full of extravasated erythrocytes). They perform similar scavenger functions in the pleural and peritoneal cavities. In lymph nodes, macrophages line the walls of sinuses and remove particulate matter from lymph as it percolates through them. In the spleen and liver, macrophages are involved in particle removal and in the detection and destruction of aged or damaged erythrocytes. They begin the degradation of haemoglobin for recycling iron and amino acids.
Macrophages bear surface receptors for the Fc portions of antibodies and for the C3 component of complement. Phagocytic activity is greatly increased when the target has been coated in antibody (opsonized) or complement, or both. Once phagocytosis has occurred, the vacuole bearing the ingested particle fuses with endosomal vesicles which contain a wide range of lysosomal enzymes, including many hydrolases, and oxidative systems capable of rapid bacteriocidal action. These activities are much enhanced when macrophages are stimulated (activated macrophages) by cytokines, e.g. interferon (IFN)-γ, which are secreted by other cells of the immune system, especially T lymphocytes.

Close antibody-mediated binding may initiate the release of lysosomal enzymes onto the surfaces of the cellular targets to which the macrophages bind. This process of cytotoxicity is also used by other cells, including neutrophils and eosinophils, particularly if the targets are too large to be phagocytosed (e.g. nematode worm parasites).

**Secretory activities**

Activated macrophages can synthesize and secrete various bioactive substances, e.g. IL-1, which stimulate the proliferation and maturation of other lymphocytes, greatly amplifying the reaction of the immune system to foreign antigens. They also synthesize tumour necrosis factor (TNF)-α, which is able to kill small numbers of neoplastic cells. TNF-α depresses the anabolic activities of many cells in the body, and may be a major factor mediating cachexia (wasting) which typically accompanies more advanced cancers. Other macrophage products include plasminogen activator, which promotes clot removal; various lysosomal enzymes; several complement and clotting factors; and lysozyme (an antibacterial protein). In pathogenesis, these substances may be released inappropriately and damage healthy tissues, e.g. in rheumatoid arthritis and various other inflammatory conditions.
DENDRITIC CELLS

There are two distinct groups of dendritic cell, myeloid dendritic cells (also known as conventional dendritic cells) and plasmacytoid dendritic cells. Both groups of cells are derived from haematopoietic stem cells. Until recently it was thought that plasmacytoid dendritic cells were derived from the lymphoid precursor cells, while the myeloid dendritic cells were derived from the myeloid progenitor cell. However, it is now apparent that these cells can be derived from either lineage, possibly from a common stem cell indicating considerable plasticity in their developmental pathways. Both cells are involved in antigen presentation, though have somewhat different functional roles in controlling both the adaptive and innate immune system. The myeloid dendritic cells are professional antigen-presenting cells (APC), which are able to process and present antigen to T lymphocytes, including naïve T cells. They are present as immature dendritic cells in the epidermis of the skin (Fig. 4.14) and other stratified squamous epithelia, e.g. the oral mucosa (Langerhans cells), and in the dermis and most other tissues (interstitial dendritic cells), where they are concerned with immune surveillance. Immature dendritic cells have an antigen-capturing function. They respond to chemotactic signals, for example defensins released by epithelial cells in the small intestine and they express pattern recognition receptors (e.g. Toll-like receptors) on their surface. Binding of bacterial molecules (e.g. carbohydrate or DNA) to these receptors stimulates the dendritic cells to migrate via the lymphatics to nearby secondary lymphoid tissues where they mature and acquire an antigen-presenting function. Mature dendritic cells are known as veiled cells when in the afferent lymphatics and the subcapsular sinuses of lymph nodes, and as interdigitating dendritic cells once they are within the lymphoid tissue proper. Their function within the secondary lymphoid tissue is to present their processed antigen to T lymphocytes, and thus to initiate and stimulate the immune response. For a review of recent research on dendritic cell function, see Colonna et al (2006).

Langerhans cells

Langerhans cells (Fig. 4.14) are one of the most well-studied types of immature dendritic cell (reviewed in Berger et al 2006). They are present throughout the epidermis of skin, where they were first described, but are most clearly identifiable in the stratum spinosum (see Ch. 7). They have an irregular nucleus and a clear cytoplasm, and contain characteristic elongated membranous vesicles (Birbeck granules). Langerhans cells endocytose and process antigens, undergoing a process of maturation from antigen-capturing to antigen-presenting cells which express high levels of MHC class I and II molecules, co-stimulatory molecules and adhesion molecules. They migrate to lymph nodes to activate T lymphocytes.

Interdigitating dendritic cells
Immature dendritic cells are found all over the body, including peripheral blood, and function in antigen-processing and immune surveillance. Mature dendritic cells are present in T cell-rich areas of secondary lymphoid tissue (paracortical areas of lymph nodes, interfollicular areas of MALT, periarteriolar sheaths of splenic white pulp), where they are frequently referred to as interdigitating dendritic cells. Within the secondary lymphoid tissues, they are involved in the presentation to T lymphocytes of antigens associated with either MHC class I (CD8 T cells) or MHC class II (CD4 T cells) molecules. Naïve T cells can only respond to antigen presented by dendritic cells. The T cells are stimulated not only by recognition of the antigen-MHC complex by the TcR, but also by interaction with co-stimulatory molecules expressed by the dendritic cells, and by cytokines secreted by the cells. These cytokines not only help activate the T cell but can also direct the nature of the T-cell response (e.g. Th1 or Th2). Appropriate T cells are thus activated to proliferate and are primed for carrying out their immunological functions. Once primed, T cells can then be stimulated by any APC, including macrophages and B cells.

**Follicular dendritic cells**

Follicular dendritic cells, FDCs (Fig. 4.15), are a non-migratory population of cells found in the follicles of secondary lymphoid tissues, where they attract and interact with B cells. Unlike other dendritic cells, FDCs are not haemopoietic in origin, but are probably derived from the stromal cells of lymphoid tissues. They are unable to endocytose and process antigen, and they lack MHC class II molecules. However, Fc receptors and complement receptors CD21 and CD35 on FDCs allow the cells to bind immune complexes to their surface for subsequent presentation, as unprocessed antigen, to germinal centre B cells. Interactions between B cells, CD4 helper T cells and FDCs in the germinal centres are important in the selection of high affinity B cells and their maturation to either plasma cells or memory B lymphocytes.

CHAPTER 5 – Functional anatomy of the musculoskeletal system

The skeletal system consists of the specialized supporting connective tissues of the bony skeleton and the associated tissues of joints, including cartilage. Cartilage is the fetal precursor tissue in the development of many bones; it also supports non-skeletal structures, as in the ear, larynx and tracheobronchial tree. Bone provides a rigid framework which protects and supports most of the soft tissues of the body and acts as a system of struts and levers which, through the action of attached skeletal muscles, permits movement of the body. Bones of the skeleton are connected with each other at joints which, according to their structure, allow varying degrees of movement. Some joints are stabilized by fibrous tissue connections between the articulating surfaces, while others are stabilized by tough but flexible ligaments. Skeletal muscles are attached to bone by strong flexible, but inextensible, tendons which insert into bone tissue. The entire assembly forms the musculoskeletal system; all its cells are related members of the connective tissue family and are derived from mesenchymal stem cells.

CARTILAGE

During early fetal life the human skeleton is mostly cartilaginous, but is subsequently largely replaced by bone. In adults, cartilage persists at the surfaces of synovial joints, in the walls of the larynx and epiglottis, trachea, bronchi, nose and external ears. Developmental replacement by bone is a complex process: cells in cartilaginous growth plates – which lie between ossifying epiphyses and the diaphyses of long bones (and elsewhere) – continue to proliferate, increasing the length of the bones concerned until they eventually ossify, when growth ceases.

MICROSTRUCTURE OF CARTILAGE

Cartilage is a type of load-bearing connective tissue. It has a low metabolic rate and its vascular supply is confined to its surface or to large cartilage canals. It has a capacity for continued and often rapid interstitial and appositional growth, and a high resistance to tension, compression and shearing, with some resilience and elasticity. Cartilage is covered by a fibrous perichondrium except at its junctions with bone and at synovial surfaces, which are lubricated by a secreted nutrient synovial fluid.

The cells of cartilage are chondroblasts and chondrocytes. Like connective tissues generally, the extracellular matrix is a dominant component and gives the tissue its distinguishing characteristics. The extracellular matrix of cartilage varies in appearance, composition and in the nature of its fibres in the different types of cartilage, namely, hyaline cartilage, white fibrocartilage and yellow elastic cartilage. A densely cellular cartilage, with thin septa of matrix between its cells, is typical of early embryonic cartilage. Hyaline cartilage is the prototypical form but it varies more in composition and properties according to age and location, than either elastic or fibrocartilage. Hyaline cartilage may become calcified as part of the normal process of bone development, or as an age-related, degenerative change.

Cartilage cells occupy small lacunae in the matrix which they secrete. Young cells (chondroblasts) are smaller, often flat and irregular in contour, and bear many surface processes, which fit into complementary recesses in the matrix. Newly generated chondroblasts often retain intercellular contacts, including gap junctions. These are
lost when daughter cells are separated by the synthesis of new matrix. As cartilage cells mature, they lose the ability to divide and become metabolically less active. Some authors reserve the name chondrocytes for such cells, but this term is commonly employed, as it is here, to denote all cartilage cells embedded in matrix. Mature chondrocytes enlarge with age and become more rounded. The ultrastructure of chondrocytes is typical of cells which are active in making and secreting proteins. The nucleus is round or oval, euchromatic and possesses one or more nucleoli. The cytoplasm is filled with rough endoplasmic reticulum, transport vesicles and Golgi complexes, and contains many mitochondria and frequent lysosomes, together with numerous glycogen granules, intermediate filaments (vimentin) and pigment granules. When these cells mature to the relatively inactive chondrocyte stage, the nucleus becomes heterochromatic, the nucleolus smaller, and the protein synthetic machinery much reduced: the cells may also accumulate large lipid droplets.

Cartilage is often described as totally avascular. Most cartilage cells are usually distant from exchange vessels, which are mostly perichondrial, and so nutrient substances and metabolites diffuse along concentration gradients across the matrix between the perichondrial capillary network and chondrocytes. This limitation is reflected in the fact that most living cartilage tissue is restricted to a few millimetres in thickness. Cartilage cells situated further than this from a nutrient vessel do not survive, and their surrounding matrix typically becomes calcified. In the larger cartilages and during the rapid growth of some fetal cartilages, vascular cartilage canals penetrate the tissue at intervals, providing an additional source of nutrients. In some cases these canals are temporary structures, but others persist throughout life.

**Extracellular matrix**

The extracellular matrix is composed of collagen and, in some cases, elastic fibres, embedded in a highly hydrated but stiff ground substance (Fig. 5.1). The components are unique to cartilage, and endow it with unusual mechanical properties. The ground substance is a firm gel, rich in carbohydrates and predominantly acidic. The chemistry of the ground substance is complex. It consists mainly of water and dissolved salts, held in a meshwork of long interwoven proteoglycan molecules together with various other minor constituents, mainly proteins or glycoproteins.
Collagen forms up to 50% of the dry weight of cartilage. It is chemically distinct from the collagen in most other tissues, and is classed as type II collagen. This variety is only found elsewhere in the notochord, the nucleus pulposus of the intervertebral disc, the vitreous body of the eye, and the primary corneal stroma. Its tropocollagen subunits are composed of triple helices of identical polypeptides (three α-1 chains). Collagen in the outer layers of the perichondrium and much of the collagen in white fibrocartilage is the general connective tissue type I.
The majority of the collagen fibres of cartilage are relatively short and thin (mainly 10–20 nm diameter), with a characteristic cross-banding (65 nm periodicity). They are interwoven to create a three-dimensional meshwork linked by lateral projections of the proteoglycans associated with their surfaces. Proteoglycans and other organic molecules link collagen fibres with the interfibrillar ground substance and with chondrocytes. The amount, size and orientation of collagen fibres vary in different types of cartilage, and with maturity and position within the cartilage mass. In articular cartilage, collagen fibres close to the surfaces of cells are particularly narrow (4–6 nm diameter) and resemble fibres of type II collagen in non-cartilaginous tissue, i.e. the vitreous body of the eye. Cartilage contains minor quantities of other classes unique to cartilage, including types IX, X and XI.

Proteoglycans and glycosaminoglycans (GAGs)

Proteoglycans are similar in general outline to those of general connective tissue, although with features peculiar to cartilage. Chondroitin sulphate and keratan sulphate play important roles in the water retention properties of cartilage.

Synthesis of matrix

Chondrocytes synthesize and secrete all of the major components of the matrix. Collagen is synthesized within the rough endoplasmic reticulum in the same way as in fibroblasts, except that type II rather than type I procollagen chains are made. These assemble into triple helices and some carbohydrate is added at this stage. After transport to the Golgi apparatus, where further glycosylation occurs, they are secreted as procollagen molecules into the extracellular space. Here, terminal registration peptides are cleaved from their ends, so forming tropocollagen molecules, and final assembly into collagen fibres takes place. Core proteins of the proteoglycan complexes are also synthesized in the rough endoplasmic reticulum and addition of GAG chains begins. The process is completed in the Golgi complex. Hyaluronan, which lacks a protein core, is synthesized by enzymes on the surface of the chondrocyte; it is not modified post-synthetically, and is extruded directly into the matrix without passing through the endoplasmic reticulum.

Hyaline cartilage

Hyaline cartilage has a homogeneous glassy, bluish opalescent appearance. It has a firm consistency and some elasticity. Costal, nasal, some laryngeal, tracheobronchial, all temporary (developmental) and most articular, cartilages are hyaline. The arytenoid cartilage changes from hyaline at its base, to elastic cartilage at its apex. Size, shape and arrangement of cells, fibres and proteoglycan composition vary at different sites and with age. The chondrocytes are flat near the perichondrium and rounded or angular, deeper in the tissue. They are often grouped in pairs, sometimes more, forming cell nests (isogenous cell groups) which are daughter cells of a common parent chondroblast: apposing cells have a straight outline. The matrix is typically basophilic (Fig. 5.2) and metachromatic, particularly in the lacunar capsule, where recently formed, territorial matrix borders the lacuna of a chondrocyte. The paler-staining interterritorial matrix between cell nests is older synthetically. Fine collagen fibres are arranged in a basket-like network (Fig. 5.3), but are often absent from a narrow zone immediately surrounding the lacuna. An isogenous cell group, together with the enclosing pericellular matrix, is sometimes referred to as a chondron.
Fig. 5.2 Sections through hyaline cartilage. A. Low-power view of human rib, showing perichondrium (P, left), young chondroblasts (Cb) embedded in pale-staining interterritorial matrix and mature chondrocytes (Cc) embedded in the basophilic interterritorial matrix (centre and right). B. Higher magnification of hyaline cartilage in human bronchial wall, showing isogenous groups of chondrocytes (C). Note the more deeply-stained basophilic zones (B) (rich in acidic proteoglycans) around the cell clusters, with older, paler-staining matrix (M) between clusters.
After adolescence, hyaline cartilages are prone to calcification, especially in costal and laryngeal sites. In costal cartilage, the matrix tends to fibrous striation, especially in old age when cellularity diminishes. The xiphoid process and the cartilages of the nose, larynx and trachea (except the elastic cartilaginous epiglottis and corniculate cartilages) resemble costal cartilage in microstructure. The regenerative capacity of hyaline cartilage is poor.

**Articular hyaline cartilage**

Articular hyaline cartilage covers articular surfaces in synovial joints (Fig. 5.4). It provides an extremely smooth, resistant surface bathed by synovial fluid, which allows almost frictionless movement. Its elasticity, together with that of other articular structures, dissipates stresses, and gives the whole articulation some flexibility, particularly near extremes of movement. Articular cartilage is particularly effective as a shock-absorber, and resists the large compressive forces generated by weight transmission, especially during movement.
Fig. 5.4 Articular cartilage from the anterior region of the lateral femoral condyle of a young adult human female. Shown are the articular surface (top), articular cartilage and subchondral bone (below). Note the changes in size and spatial distribution of articular chondrocytes through the thickness of the cartilage. 3-D digital volumetric fluorescence imaging of serially sectioned, eosin-Y and acridine orange-stained tissue.  
(Provided by courtesy of Professor Robert L Sah, Drs Won C Bae, Kyle D Jadin, Benjamin L Wong, Kelvin W. Li and Mrs Barbara L. Schumacher, Department of Bioengineering and Whitaker Institute of Biomedical Engineering, University of California, San Diego.)

Articular cartilage does not ossify. It varies from 1 to 7 mm in thickness and is moulded to the shape of the underlying bone, indeed it often accentuates and modifies the surface geometry of the bone. It is thickest centrally on convex osseous surfaces, and the reverse is true of concave surfaces. Its thickness decreases from maturity to old age. The surface of articular cartilage lacks a perichondrium; synovial membrane overlaps and then merges into its structure circumferentially (see Fig.
Fig. 5.32 A section of a synovial joint and its associated highly vascular (red) synovial membrane in a human fetal hand. The two articular cartilage surfaces (A, arrowed) are separated on the right by a layer of synovial fluid (S) secreted by the synovial membrane (SM) which extends a short distance into the joint space from the capsule (C).

Adult articular cartilage shows a structural zonation with increasing depth from the surface. The arrangement of collagen fibres has been variously described as plexiform, helical, or in the form of serial arcades which radiate from the deepest zone to the surface, where they follow a short tangential course before returning radially. If the surface of an articular cartilage is pierced by a needle, a longitudinal split-line remains after withdrawal. For any given joint, the patterns of split-lines are constant and distinctive and follow the predominant directions of collagen bundles in tangential zones of cartilage. These patterns may reveal tension trajectories set up in surrounding cartilage during joint movement.

Zone 1 is the superficial or tangential layer. The free articular surface is a thin, cell-free layer, 3 µm thick, which contains fine collagen type II fibrils covered superficially by a protein coating. The cells are small, oval or elongated and parallel to the surface, relatively inactive, and surrounded by fine tangential fibres. The collagen fibres deeper within this zone are regularly tangential, their diameters and density increase with depth. Zone 2 is the transitional or intermediate layer. The cells are larger, rounder, and are either single or in isogenous groups. Most are typical active chondrocytes, surrounded by oblique collagen fibres. Deeper still, in the radiate layer (zone 3), cells are large, round and often disposed in vertical columns, with intervening radial collagen fibres. As elsewhere, the cells, either singly or in groups, are encapsulated in
pericellular matrix which has fine fibrils and contains fibronectin and types II, IX and XI collagen. The deepest layer or calcified layer (zone 4) lies adjacent to the subchondral bone (hypochondral osseous lamina) of the epiphysis. The adjacent surfaces show reciprocal fine ridges, grooves and interdigitations, which, with the confluence of their fibrous arrays, resist shearing stresses produced by postural changes and muscle action. The junction between zones 3 and 4 is called the tidemark. With age, articular cartilage thins and degenerates by advancement of the tidemark zone, and the replacement of calcified cartilage by bone.

Concentrations of GAGs vary according to site and, in particular, with age. The proportion of keratan sulphate increases linearly with depth, mainly in the older matrix between cell nests, whereas chondroitin sulphates are concentrated around lacunae. The turnover rates of GAGs in cartilage are faster than those of collagen, and the smaller, more soluble GAGs turn over fastest. Turnover decreases with age and distance from the cells. The proteoglycan turnover time is estimated at nearly 5 years for adult human articular cartilage.

The sequence of structural features outlined above is also typical of cartilaginous growth plates (see p. 95). During radial epiphysial growth, the extension of endochondral ossification into overlying calcified cartilage starts with the development of isogenous groups followed by the appearance of hypertrophic cells arranged in vertical columns. This ceases in maturity, but the zones persist throughout life. The same terminal mechanism also occurs in bones which lack epiphyses.

Cells of articular cartilage are capable of cell division, but mitoses are rare except in young bones and damage is not repaired in the adult. Superficial cells are lost progressively from normal young joint surfaces, and they are replaced by cells from deeper layers. Degenerating cells may occur in any of the four zones. This probably accounts for the progressive reduction in cellularity of cartilage with advancing age, particularly in superficial layers.

Articular cartilages derive nutrients by diffusion from vessels of the synovial membrane, synovial fluid and hypochondral vessels of an adjacent medullary cavity, some capillaries from which penetrate and occasionally traverse the calcified cartilage. The contributions from these sources are uncertain and may change with age. Small molecules freely traverse articular cartilage, with diffusion coefficients about half those in aqueous solution. Larger molecules have diffusion coefficients inversely related to their molecular size. The permeability of cartilage to large molecules is greatly affected by variations in its GAG, and hence water, content, e.g. a three-fold increase multiplies the diffusion coefficient a hundred-fold.

**Fibrocartilage**

Fibrocartilage is dense, fasciculated, opaque white fibrous tissue. It contains fibroblasts and small interfascicular groups of chondrocytes. The cells are ovoid and surrounded by concentrically striated matrix (Fig. 5.5). When present in quantity, as in intervertebral discs, fibrocartilage has great tensile strength and appreciable elasticity. In lesser amounts, as in articular discs, the glenoid and acetabular labra, and the cartilaginous lining of bony grooves for tendons and some articular cartilages, it provides strength, elasticity and resistance to repeated pressure and friction. It is resistant to degenerative change.
Fibrocartilage is unlike other types of cartilage in that it contains a considerable amount of type I (general connective tissue) collagen which is synthesized by the fibroblasts in its matrix. It is perhaps best regarded as a mingling of the two types of tissue, e.g. where a ligament or tendinous tissue inserts into hyaline cartilage, rather than as a separate type of cartilage. However, fibrocartilage in joints often lacks type II collagen altogether, and so possibly represents a distinct class of connective tissue.

The articular surfaces of bones which ossify in mesenchymal membranes (e.g. squamous temporal, mandible and clavicle) are covered by white fibrocartilage. The
deep layers, adjacent to hypochondral bone, resemble calcified regions of the radial zone of hyaline articular cartilage. The superficial zone contains dense parallel bundles of thick collagen fibres, interspersed with typical dense connective tissue fibroblasts and little ground substance. Fibre bundles in adjacent layers alternate in direction, as they do in the cornea. A transitional zone of irregular bundles of coarse collagen and active fibroblasts separates the superficial and deep layers. The fibroblasts are probably involved in elaboration of proteoglycans and collagen, and may also constitute a germinal zone for deeper cartilage. Fibre diameters and types may differ at different sites according to the functional load.

Elastic cartilage

Elastic cartilage occurs in the external ear, corniculate cartilages, epiglottis and apices of the arytenoids. It contains typical chondrocytes, but its matrix is pervaded by yellow elastic fibres, except around lacunae (where it resembles typical hyaline matrix with fine type II collagen fibrils) (Fig. 5.6). Its elastic fibres are irregularly contoured and show no periodic banding. Most sites in which elastic cartilage occurs have vibrational functions, such as laryngeal sound wave production, or the collection and transmission of sound waves in the ear. Elastic cartilage is resistant to degeneration; it can regenerate to a limited degree following traumatic injury, e.g. the distorted repair of a ‘cauliflower ear’.

![Fig. 5.6 Elastic cartilage, stained to demonstrate elastin fibres (blue-black). Chondroblasts and larger chondrocytes are embedded in the matrix, which also contains collagen type II fibres.](image-url)
DEVELOPMENT AND GROWTH OF CARTILAGE

Cartilage is usually formed in embryonic mesenchyme. Mesenchymal cells proliferate and become tightly packed: the shape of their condensation foreshadows that of the future cartilage. They also become rounded, with prominent round or oval nuclei and a low cytoplasm: nucleus ratio. Adjacent cells are linked by gap junctions. Each cell next secretes a basophilic halo of matrix, composed of a delicate network of fine type II collagen filaments, type IX collagen and cartilage proteoglycan core protein, i.e. it differentiates into a chondroblast (Fig. 5.7). In some sites, continued secretion of matrix separates the cells, producing typical hyaline cartilage. Elsewhere, many cells become fibroblasts: collagen synthesis predominates and chondroblastic activity appears only in isolated groups or rows of cells which become surrounded by dense bundles of collagen fibres to form white fibrocartilage. In yet other sites, the matrix of early cellular cartilage is permeated first by anastomosing oxytalan fibres, and later by elastin fibres. In all cases, developing cartilage is surrounded by condensed mesenchyme which differentiates into a bilaminar perichondrium. The cells of the outer layer become fibroblasts and secrete a dense collagenous matrix lined externally by vascular mesenchyme. The cells of the inner layer contain differentiated, but mainly resting, chondroblasts or prechondroblasts.

**Fig. 5.7** Highly cellular fetal cartilage, human phalanx. The cells are small and almost uniform in distribution. Mallory's triple stain.

Cartilage grows by interstitial and appositional mechanisms. Interstitial growth is the result of continued mitosis of early chondroblasts throughout the tissue mass and is
obvious only in young cartilage, where plasticity of the matrix permits continued expansion. When a chondroblast divides, its descendants temporarily occupy the same lacuna. They are soon separated by a thin septum of secreted matrix, which thickens and further separates the daughter cells. Continuing division produces isogenous groups. Appositional growth is the result of continued proliferation of the cells that form the internal, chondrogenic layer of the perichondrium. Newly formed chondroblasts secrete matrix around themselves, creating superficial lacunae beneath the perichondrium. This continuing process adds additional surface, while the entrapped cells participate in interstitial growth. Apposition is thought to be most prevalent in mature cartilages, but interstitial growth must persist for long periods in epiphysial cartilages. Relatively little is known about the factors which determine the overall shape of a cartilage.
**BONE**

Bone, and the struts and levers which it forms, is exquisitely adapted to resist stress with suitable resilience, support the body and provide leverage for movement. It is a highly vascular mineralized connective tissue: the great majority of its cells are embedded in an extracellular matrix composed of organic materials (about 40% dry weight in mature bone) and inorganic salts rich in calcium and phosphate.

**MACROSCOPIC ANATOMY OF BONE**

Macroscopically, living bone is white. Its texture is either dense like ivory (compact bone), or honeycombed by large cavities (trabecular, cancellous or spongy bone), where the bony element is reduced to a latticework of bars and plates (trabeculae) (Fig. 5.8, Fig. 5.9). Compact bone is usually limited to the cortices of mature bones (cortical bone) and is of great importance in providing their strength. Its thickness and architecture vary for different bones, according to their overall shape, position and functional roles. The cortex plus the hollow medullary canal of long bones allows combination of strength with low weight. Cancellous bone is usually internal, giving additional strength to cortices and supporting the bone marrow. Bone forms a reservoir of metabolic calcium (99% of body calcium is in the bony skeleton) and phosphate which is under hormonal and cytokine control.
**Fig. 5.8** Vertical section 2 cm below the anterosuperior border of the iliac crest (female, 42 years). The cancellous bone consists of intersecting curved plates and struts. Osteonal (Haversian) canals can just be seen in the two cortices (C) at this magnification.
The proportions of compact to cancellous bone vary greatly. In long bones, the diaphysis consists of a thick cylinder of compact bone with a few trabeculae and spicules on its inner surface. It encloses a large central medullary or marrow cavity that communicates freely with the intratrabecular spaces of the expanded bone ends. In other bones, especially flat bones such as the ribs, the interior is uniformly cancellous, and compact bone forms the surface. The cavities are usually filled with marrow, either red haemopoietic or yellow adipose, according to age and site. However, in some bones of the skull, notably the mastoid process of the temporal
bone, and the paranasal sinuses of the maxilla, sphenoid and ethmoid, many of the internal cavities are filled with air, i.e. they are pneumatized.

Bones vary not only in their primary shape but also in lesser surface details, or secondary markings, which appear mainly in postnatal life. Most bones display features such as elevations and depressions (fossae), smooth areas and rough ridges. Numerous names are used to describe these secondary features. Some articular surfaces are called fossae (e.g. the glenoid fossa); lengthy depressions are grooves or sulci (e.g. the humeral bicipital sulcus); a notch is an incisura, and an actual gap is a hiatus. A large projection is termed a process or, if elongated and slender or pointed, a spine. A curved process is a hamulus or cornu (e.g. the pterygoid hamuli of the sphenoid bone and the cornua of the hyoid). A rounded projection is a tuberosity or tubercle, and occasionally a trochanter. Long elevations are crests, or lines, if they are less developed; crests are wider and present boundary edges or lips. An epicondyle is a projection close to a condyle and is usually a site where the common tendon of a superficial muscle group or the collateral ligament of the adjacent joint are attached. The terms protuberance, prominence, eminence and torus are less often applied to certain bony projections. The expanded proximal ends of many long bones are often termed the ‘head’ or caput (e.g. humerus, femur, radius). A hole in bone is a foramen, and becomes a canal when lengthy. Large holes may be called apertures or, if covered largely by connective tissue, fenestrae. Clefts in or between bones are fissures. A lamina is a thin plate; larger laminae may be called squamae (e.g. the temporal squama). Large areas on many bones are featureless and often smoother than articular surfaces, from which they differ because they are pierced by many visible vascular foramina. This texture occurs where muscle is directly attached to bone, and small blood vessels pass through the foramina from bone to muscle, and perhaps vice versa. Areas covered only by periosteum are similar, but vessels are less numerous.

Tendons are usually attached at roughened bone surfaces. Wherever any aggregation of collagen in a muscle reaches bone, surface irregularities correspond in form and extent to the pattern of such ‘tendinous fibres’. Such markings are almost always elevated above the general surface, as if ossification advanced into the collagen bundles from periosteal bone. How such secondary markings are induced is uncertain but they may result from the continued incorporation of new collagen fibres into the bone, perhaps necessary for minor functional adjustment. Evidence suggests that their prominence may be related to the power of the muscles involved and they increase with advancing years, as if the pull of muscles and ligaments exercised a cumulative effect over a limited area. Surface markings delineate the shape of attached connective tissue structures, whether these are an obvious tendon, intramuscular tendon or septum, aponeurosis, or tendinous fibres mediating what is otherwise a direct muscular attachment. These markings may be facets, ridges, nodules, rough areas or complex mixtures: they afford accurate indications of the junctions of bone with muscles, tendons, ligaments or articular capsules.

When a muscle is apparently attached directly to bone, its fibres do not themselves adhere directly to periosteum or bone. The route of transmission of tension from contracting muscle to bone is through the connective tissue that encapsulates (epimysium) and pervades (perimysium and endomysium) all muscles. These two forms of attachment of muscles, which are at the extremes of a range of admixtures, differ in the density of collagen fibres between muscle and bone. Where collagen is
visibly concentrated, markings appear on the bone surface. In contrast, the multitude of microscopic connective tissue ties of direct attachment that occur over a larger area do not visibly mark the bone, and so it appears smooth to unaided vision and touch.

Bones display articular surfaces at synovial joints with their neighbours: if small, these are termed facets or foveae, larger, knuckle-shaped surfaces are condyles, and a trochlea is grooved like a pulley. Articular surfaces are smooth and adapted in shape to the movement of particular joints. In life they are covered by articular cartilage; they are smooth partly because they lack the vascular foramina typical of most other bone surfaces. Large tendons, e.g. those of adductor magnus and subscapularis, are attached to facets which lack the regular contours of articular surfaces, but which resemble them in texture, because they are poorly vascularized. These facets are sometimes depressed, but they may surmount large elevations, e.g. the humeral tubercles.
MICROSTRUCTURE OF BONE

Bone contains a mineralized extracellular matrix; specialized cells including osteoblasts, osteocytes and osteoclasts; and components of the periosteum, endosteum and marrow. These components will be described in detail below, first individually, and then in terms of their overall organization.

Bone matrix

Bone matrix is the mineralized extracellular material of bone; like general connective tissues, it consists of a ground substance in which numerous collagen fibres are embedded, usually ordered in parallel branching arrays (Fig. 5.10). In mature bone, the matrix is moderately hydrated, and 10–20% of its mass is water. Of its dry weight, 60–70% is made up of inorganic, mineral salts (mainly microcrystalline calcium and phosphate hydroxides, hydroxyapatite (see below), approximately 30% is collagen and the remainder is non-collagenous protein and carbohydrate, mainly conjugated as glycoproteins. The proportions of these components vary with age, location and metabolic status.
Collagen

The collagen that is found in bone closely resembles that of many other connective tissues, and is mainly type I: there are trace amounts of type V which is thought to regulate fibrillogenesis. However, its molecular structure is unlike that of collagen in general connective tissue: it displays internal covalent cross-linkages, and the transverse spacings within its fibrils are somewhat larger. The cross-links make it stronger and chemically more inert, and the internal gaps provide the space for deposition of minerals. Up to two-thirds of the mineral content of bone is thought to be located within collagen fibrils. Crystal formation is probably initiated in the hole zones, which are gaps between the ends of tropocollagen subunits.
Collagen contributes greatly to the mechanical strength of bone, although its precise role in bone mechanics has yet to be clarified. As well as contributing to the tensile, compressive and shearing strengths of bone, the small degree of elasticity shown by collagen imparts a measure of resilience to the tissue, and helps to resist fracture when bone is mechanically loaded.

Collagen fibres are synthesized by osteoblasts, polymerize from tropocollagen extracellularly, and become progressively more cross-linked as they mature. In primary bone, they form a complex interwoven meshwork of non-lamellar woven or bundle bone, which in most sites is almost entirely replaced by regular laminar arrays of nearly parallel collagen fibres (lamellar bone). Partially mineralized collagen networks can be seen within osteoid on the outer and internal surfaces of bone, and in the endosteal linings of vascular canals. Collagen fibres from the periosteum are incorporated in cortical bone (extrinsic fibres), and anchor this fibrocellular layer at its surface. Terminal collagen fibres of tendons and ligaments are incorporated deep into the matrix of cortical bone. They may be interrupted by new osteons during cortical drift (modelling) and turnover (remodelling), and remain as islands of interstitial lamellae or even trabeculae.

Non-collagenous organic components

Small amounts of various complex macromolecules are attached to collagen fibres and surrounding bone crystals. These are secreted by osteoblasts and young osteocytes and include osteonectin, osteocalcin, the bone proteoglycans biglycan and decorin, the bone sialoproteins osteopontin and thrombospondin, many growth factors including transforming growth factor \( \beta \) (TGF-\( \beta \)), proteases and protease inhibitors, often in a latent form. The functions of some of these molecules are described with osteoblasts (see below).

Bone minerals

Bone minerals are the inorganic constituents of the bone matrix. They confer the hardness and much of the rigidity of bone, and are the main reason that bone is easily seen on radiographs (bone has to be 50% mineralized to be visible on radiographs produced with a standard X-ray unit). The mineral substances of bone are mostly acid-soluble. If they are removed, using calcium chelators such as citrates or ethylene diamine tetra-acetic acid (EDTA), the bone retains its shape but becomes highly flexible.

The mineral portion of mature bones is composed largely of crystals made of a substance generally referred to as hydroxyapatite (but with an important carbonate content, and a lower Ca/P ratio than pure hydroxyapatite \( \text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2 \)), together with a small amount of calcium phosphate. Bone crystals are small but have a large surface area. They take the form of thin plates or leaf-like structures and range in size up to 150 nm long × 80 nm wide × 5 nm thick, although most are half that size. They are often packed quite closely together, with their long axes nearly parallel to the axes of the collagen fibrils. The narrow gaps between the crystals contain associated water and organic macromolecules.

The major ions which make up the mineral part of bone include calcium, phosphate, hydroxyl and carbonate. Less numerous ions are citrate, magnesium, sodium,
potassium, fluoride, chloride, iron, zinc, copper, aluminium, lead, strontium, silicon and boron, many of which are present only in trace quantities. Fluoride ions can substitute for hydroxyl ions, and carbonate can substitute for either hydroxyl or phosphate groups. Group IIA cations, e.g. radium, strontium and lead, all readily substitute for calcium and are therefore known as bone-seeking cations. Since they can be either radioactive or chemically toxic, their presence in bone, where they may be close to haemopoietic bone marrow, may cause illness and characteristic appearances on X-rays.

The concentration of mineral in young osteons is low but increases with age: it is highest in the older, more peripheral, lamellae. Mineral distribution is uniform in established, highly mineralized, osteons. Mineralization normally reaches 70–80% in 3 weeks. Immature woven bone mineralizes faster and can be identified from adjacent lamellar bone by its higher degree of mineralization. Osteons may show one or more highly mineralized arrest lines within their walls.

**Osteoblasts**

Osteoblasts are derived from osteoprogenitor (stem) cells of mesenchymal origin, which are present in the bone marrow and other connective tissues. They proliferate and differentiate, stimulated by bone morphogenetic proteins (BMPs), into osteoblasts prior to bone formation. Osteoblasts are basophilic, roughly cuboidal mononuclear cells 15–30 µm across. Ultrastructurally, they have features typical of protein-secreting cells. They are found on the forming surfaces of growing or remodelling bone, where they constitute a covering layer (Fig. 5.11). In relatively quiescent adult bones they appear to be present mostly on endosteal rather than periosteal surfaces, but they also occur deep within compact bone where osteons are being remodelled. They are responsible for the synthesis, deposition and mineralization of the bone matrix, which they secrete. Once embedded in the matrix, they become osteocytes.
Osteoblasts contain prominent bundles of actin, myosin and other cytoskeletal proteins which are associated with the maintenance of cell shape, attachment and motility. Their plasma membranes display many extensions, some of which contact neighbouring osteoblasts and embedded osteocytes at intercellular gap junctions. This arrangement facilitates coordination of the activities of groups of cells, e.g. in the formation of large domains of parallel collagen fibres.

Osteoblasts synthesize and secrete organic matrix, i.e. type I collagen, small amounts of type V collagen, and numerous other macromolecules involved in bone formation and resorption. Collagen synthesis occurs in the rough endoplasmic reticulum and Golgi apparatus, and type I collagen is secreted as monomers which assemble into the triple helical procollagen extracellularly. Other glycoprotein products include osteocalcin, which is required for bone mineralization, binds hydroxyapatite and calcium, and is used as a marker of new bone formation; osteonectin, a phosphorylated glycoprotein which binds strongly to hydroxyapatite and collagen – it may play a role in initiating hydroxyapatite crystallization, and may also be a cell adhesion factor; RANKL, the cell surface ligand for RANK (receptor for activation of nuclear factor kappa B), which is an osteoclast progenitor receptor (see below); osteoprotegerin (a soluble, high affinity decoy ligand for RANKL) which restricts osteoclast differentiation; the bone proteoglycans biglycan and decorin which bind TGF-β; bone sialoproteins, osteopontin and thrombospondin, which mediate osteoclast adhesion to bone surfaces via binding to osteoclast integrins; latent proteases and growth factors, including BMPs. TGF-β is secreted by osteoblasts as well as osteoclasts; it is activated in the acid conditions of the ruffled border zone of the osteoclast, and may be a coupling factor for stimulating new bone formation at resorption sites.

Extracellular fluid is supersaturated with respect to the basic calcium phosphates, yet mineralization is not a widespread phenomenon. Osteoblasts play a significant role in the mineralization of osteoid, the unmineralized organic matrix. They secrete osteocalcin which binds calcium weakly, but at levels sufficient to concentrate the ion locally. They also contain membrane-bound vesicles, 0.1–0.2 µm in diameter, which contain alkaline phosphatase (which can cleave phosphate ions from various molecules to elevate concentrations locally), and pyrophosphatase (which degrades inhibitory pyrophosphate in the extracellular fluid). The vesicles bud off from the cell surfaces of the osteoblasts into newly formed osteoid and are the sites of initiation of hydroxyapatite crystal formation in newly forming bone (see below). Crystals are then released into the osteoid matrix by an unknown mechanism. Some alkaline phosphatase reaches the blood circulation where it can be detected in conditions of rapid bone formation or turnover.

Osteoblasts play a key role in the hormonal regulation of bone resorption, since they express receptors for parathyroid hormone (PTH), 1,25-dihydroxy vitamin D3 and
other promoters of bone resorption. During bone resorption, osteoblasts promote osteoclast differentiation via PTH-activated expression of cell surface RANKL, which binds to RANK on immature osteoclasts, establishes cell–cell contact and triggers contact-dependent osteoclast differentiation. In the presence of PTH, osteoblasts also downregulate secretion of osteoprotegerin, a soluble decoy ligand with higher affinity for RANKL. In conditions favouring bone deposition, secreted osteoprotegerin blocks RANKL binding to RANK and restricts numbers of mature osteoclasts. (For a recent review, see Blair et al 2007.)

Bone-lining cells are flattened epithelioid cells found on the surfaces of adult bone that is not undergoing active deposition or resorption, and are generally considered to be quiescent osteoblasts or osteoprogenitor cells. They form the outer boundary of the marrow tissue on the endosteal surface of marrow cavities, are present on the periosteal surface, and line the system of vascular canals within osteons.

**Osteocytes**

Osteocytes constitute the major cell type of mature bone, and are scattered within its matrix, interconnected by numerous dendritic processes to form a complex cellular network (Fig. 5.12). They are derived from osteoblasts and are enclosed within their matrix but, unlike chondrocytes, they do not divide. Bone growth is appositional: new layers are added only to pre-existing surfaces and so, again unlike chondrocytes, osteocytes enclosed in lacunae do not secrete new matrix. The rigidity of mineralized bone matrix prevents internal expansion, which means that interstitial growth, which is characteristic of most tissues, does not occur in bone. Osteocytes retain contacts with each other and with cells at the surfaces of bone (osteoblasts and bone-lining cells) throughout their lifespan.

![Fig. 5.12](image-url) Osteocyte lacunae shown at high magnification in a dry ground section of lamellar bone. The territories of three osteocytes are shown. Their branching dendrites contact those of neighbouring cells via the canaliculi seen here within the bone matrix. Several other osteocyte lacunae are present, out of the focal plane in this section, and tangential to the osteon axis.
Mature, relatively inactive, osteocytes possess an ellipsoid cell body with the longest axis (25 µm) parallel to the surrounding bony lamella. The rather narrow rim of cytoplasm is faintly basophilic, contains relatively few organelles and surrounds an oval nucleus. Osteocytes in woven bone are larger and more irregular in shape (Fig. 5.13).

Numerous fine dendritic processes emerge from the cell body of each osteocyte and branch a number of times. They contain bundles of microfilaments and some smooth endoplasmic reticulum. At their distal tips they contact the processes of adjacent cells, i.e. other osteocytes and, at surfaces, osteoblasts and bone-lining cells. They form communicating gap junctions with these cells which means that they are in electrical and metabolic continuity.

Bone matrix surrounds the cell bodies and processes. There appears to be a variable space filled with extracellular fluid between each osteocyte and its enclosing wall. Each cell body lies in a lacuna from which many narrow, branched channels extend. These channels or canaliculi are 0.5–0.25 µm wide, and contain the dendritic processes of the osteocytes: they provide a route for the diffusion of nutrients, gases and waste products between the osteocytes and the blood vessels. Canaliculi do not usually extend through and beyond the reversal line surrounding an osteon and so do not communicate with neighbouring systems. The walls of lacunae may be lined with a variable (0.2–2 µm) layer of unmineralized organic matrix.

In well-vascularized bone, osteocytes are long-lived cells which actively maintain the
bone matrix. The average lifespan of an osteocyte varies with the metabolic activity of the bone and the likelihood that it will be remodelled, but is measured in years. Old osteocytes may retract their processes from the canaliculi; when they die, their lacunae and canaliculi may become plugged with cell debris and minerals, which hinders diffusion through the bone. Dead osteocytes occur commonly in interstitial bone and the inner regions of trabecular bone which escape surface remodelling, and are particularly noticeable by the second and third decades. Bones which experience little turnover, e.g. the auditory ossicles, are most likely to contain aged osteocytes and low osteocyte viability.

Osteocytes play an essential role in the maintenance of bone: their death leads to the resorption of the matrix by osteoclast activity. They remain responsive to parathyroid hormone and 1,25(OH)$_2$ vitamin D$_3$, and it is possible that they are involved in mineral exchange at adjacent bone surfaces. Osteocytes themselves are often mineralized.

**Osteoclasts**

Osteoclasts are large (40 µm or more) polymorphic cells containing up to 20 oval, closely packed nuclei. They lie in close contact with the bone surface in resorption bays (Howship's lacunae). Their cytoplasm contains numerous mitochondria and vacuoles, many of which are acid phosphatase-containing lysosomes. The rough endoplasmic reticulum is relatively sparse given the size of cell, but the Golgi complex is extensive. The cytoplasm also contains numerous coated transport vesicles and microtubule arrays involved in the transport of the vesicles between the Golgi stacks and the ruffled membrane, which is the highly infolded cell surface of active osteoclasts at sites of local bone resorption. A well-defined zone of actin filaments and associated proteins occurs beneath the ruffled membrane around the circumference of the resorption bay, in a region termed the sealing zone.

Functionally, osteoclasts are responsible for the local removal of bone during bone growth and subsequent remodelling of osteons and surface bone (see Fig. 5.25). They cause demineralization by proton release, which creates an acidic local environment, and organic matrix destruction by releasing lysosomal (cathepsin K) and non-lysosomal (e.g. collagenase) enzymes. Factors stimulating osteoclasts to resorb bone include osteoblast-derived signals; cytokines from other cells, e.g. macrophages and lymphocytes; blood-borne factors, e.g. parathyroid hormone and 1,25(OH)$_2$ vitamin D$_3$ (calcitriol). Calcitonin, produced by C cells of the thyroid follicle, reduces osteoclast activity.
Osteoclasts arise by fusion of monocytes derived from the bone marrow or other haemopoietic tissue. They probably share a common ancestor with macrophages within the granulocyte–macrophage lineage (see Fig. 4.12) but it is thought that they subsequently follow a distinct differentiation pathway.

**Osteons**

The mechanical properties of bone, particularly its strength and resilience, are dependent on the general composition of its matrix. Woven and lamellar bone display two quite distinct types of organization.

In woven, or bundle, bone, the collagen fibres and bone crystals are irregularly arranged. The diameters of the fibres vary, so that fine and coarse fibres intermingle, producing the appearance of the warp and weft of a woven fabric. Woven bone is typical of young fetal bones, but is also seen in adults during excessively rapid bone remodelling and repair of fractures (Fig. 5.14). It is formed by highly active osteoblasts during development, and is stimulated in the adult by fracture, growth factors, or prostaglandin E$_2$. 
Lamellar bone makes up almost all of an adult osseous skeleton (Fig. 5.15, Fig. 5.16). The precise arrangement of lamellae varies from site to site, particularly between compact cortical bone and the trabecular bone within. In many bones a few lamellae form continuous circumferential layers at the outer (periosteal) and inner (endosteal) surfaces. However, by far the greatest proportion of lamellae are arranged in concentric cylinders around neurovascular channels called Haversian canals, to form the basic units of bone tissue which are the Haversian systems or osteons. Osteons usually lie parallel with each other (Fig. 5.17) and, in elongated bones such as those of the appendicular skeleton, with the long axis of the bone. They may also spiral, branch or intercommunicate, and some end blindly.
Fig. 5.15 Main features of the microstructure of mature lamellar bone. Areas of compact and trabecular (cancellous) bone are included. Note the general construction of the osteons; distribution of the osteocyte lacunae; Haversian canals and their contents; resorption spaces. Different views of the structural basis of bone lamellation.
Fig. 5.16  A. Osteons in a dry ground transverse section of bone. Concentric lamellae surround the central Haversian canal of each complete osteon; they contain the dark lacunae of osteocytes and the canaliculi which are occupied in life by their dendrites. These canaliculi interconnect with canaliculi of osteocytes in adjacent lamellae. Incomplete (interstitial) lamellae (e.g. centre field) are the remnants of osteons remodelled by osteoclast erosion. B. High-power view of osteocytes within lamellae; a Haversian canal is seen on the right.

(B. Photograph by Sarah-Jane Smith.)
It has been estimated that there are 21 million osteons in the adult skeleton. In transverse section they are round or ellipsoidal, varying from 100 to 400 µm in diameter. A medium-sized osteon contains about 30 lamellae, each approximately 3 µm thick. Each osteon is permeated with the canaliculi of its resident osteocytes, and these form pathways for diffusion of nutrients, gases, etc. between the vascular system and the osteocytes. The maximum diameter of an osteon ensures that no osteocyte is more than 200 µm from a blood vessel, a distance that may be a limiting factor in cellular survival. The spaces between osteons contain interstitial lamellae which are the fragmentary remains of osteons and the partially eroded circumferential lamellae of older bone (see below).

The central Haversian canals of osteons vary in size, with a mean diameter of 50 µm; those near the marrow cavity are somewhat larger. Each canal contains one or two capillaries lined by fenestrated endothelium and surrounded by a basal lamina which also encloses typical pericytes. They usually contain a few unmyelinated and occasional myelinated axons. The bony surfaces of osteonic canals are perforated by the openings of osteocyte canaliculi and are lined by collagen fibres.

Haversian canals communicate with each other and directly or indirectly with the marrow cavity via vascular (nutrient) channels called Volkmann's canals, which run obliquely or at right angles to the long axes of the osteons (Fig. 5.17). The majority of these channels appear to branch and anastomose, but some join large vascular connections with vessels in the periosteum and the medullary cavity.

Osteons are distinguished from their neighbours by a cement line which contains little or no collagen, and is strongly basophilic because it has a high content of glycoproteins and proteoglycans. Cement lines mark the limit of bone erosion prior to the formation of a new osteon, and are therefore also known as reversal lines. Canaliculi occasionally pass through cement lines, and so provide a route for exchange between interstitial bone lamellae and vascular channels within osteons.
Basophilic lines can occur in the absence of erosion: they indicate where bony growth has been interrupted and then resumed and are called resting lines.

Each lamella consists of a sheet of mineralized matrix that contains collagen fibres of similar orientation locally, running in branching bundles 2–3 µm thick, and often extending the full width of a lamella. This interconnecting, three-dimensional construction increases the strength of the bone. The orientation of the collagen fibres and associated mineral crystals differs in adjacent lamellae: the difference varies between 0° and 90°, and is clearly shown by polarized light microscopy. A less perfect packing of collagen fibrils into bundles occurs at the borders of lamellae, where intermediate and random orientations predominate. The main direction of the collagen fibres within osteons of long bone shafts varies: the fibres are more longitudinal at sites which are subjected predominantly to tension, and more oblique at sites subjected mostly to compression. The peripheral lamellae of osteons contain more transverse fibres at any site in a diaphysis.

Trabecular bone

The organization of trabecular (cancellous, spongy) bone is basically lamellar, as shown most clearly under polarized light (Fig. 5.18). It takes the form of branching and anastomosing curved plates, tubes and bars of various widths and lengths which surround marrow cavities and are lined by endosteal tissue (Fig. 5.8, Fig. 5.9). Their thickness ranges from 50 to 400 µm. In general, bone lamellae are oriented parallel with the adjacent bone surface, and the arrangement of cells and matrix is similar to that found in circumferential and osteonic bone. Thick trabeculae and regions close to compact bone may contain small osteons, but blood vessels do not otherwise lie within the bony tissue, and osteocytes therefore rely on canalicular diffusion from adjacent medullary vessels. In young bone, calcified cartilage may occur in the cores of trabeculae, but this is generally replaced by bone during subsequent remodelling.
Fig. 5.18 Trabecular bone in a bone marrow sample taken from the human posterior iliac crest. A, Irregular trabeculae of bone, surrounded by bone marrow haemopoietic and adipose tissue (haematoxylin and eosin stain); B, the same field viewed under polarized light, demonstrating lamellar, non-osteonic bone with lamellae oriented in different directions in different regions. Osteocytes are just visible, embedded in the solid matrix.

Remodelling

Remodelling of the interior of a bone depends upon the balance of resorption and deposition of bone, i.e. on the balanced activities of osteoclasts and osteoblasts. Osteoclasts first excavate a cylindrical tunnel by concerted action. A ‘cutting cone’ is formed by groups of osteoclasts moving at 50 µm/day, followed by osteoblasts which fill in the space so created. The osteoblasts deposit new osteoid matrix concentrically around a centrally ingrowing blood vessel, starting at the peripheral surface of the tunnel. This forms a ‘closing cone’ with 4000 osteoblasts/mm². Deposition of successive, concentric lamellae follows, as cohorts of osteoblasts become embedded
in the matrix they secrete, and are succeeded by new osteoblasts which line the free surface thus created, and secrete the next layer. In this way the walls of resorption cavities are lined with new lamellar matrix, and the vascular channels are progressively narrowed (Fig. 5.19). The pattern and extent of remodelling is dictated by the mechanical loads applied to the bone.

**Fig. 5.19** Bone remodelling. Longitudinal and cross-sections of a time line illustrating the formation of an osteon. Osteoclasts cut a cylindrical channel through bone. Osteoblasts follow, laying down bone on the surface of the channel until matrix surrounds the central blood vessel of the newly formed osteon (closing cone of a new osteon).

A hypermineralized basophilic cement line marks a site of reversal from resorption to deposition. Formation of osteons does not end with growth but continues variably throughout life. Remnants of circumferential lamellae of old osteons form interstitial lamellae between newer osteons (Fig. 5.15, Fig. 5.16A).
It has been estimated that approximately 10% of the adult bony skeleton turns over each year by the process of remodelling. The degree of remodelling varies with age and the number of osteons and osteon fragments have therefore been used in attempts to estimate the age of skeletal material at death.

**Periosteum, endosteum and bone marrow**

The outer surface of bone is covered by a condensed, fibrocollagenous layer, the periosteum. The inner surface is lined by a thinner, more cellular, endosteum. Osteoprogenitor cells, osteoblasts, osteoclasts and other cells important in the turnover and homeostasis of bone tissue lie in these layers.

The periosteal layer is tethered to the underlying bone by extrinsic collagen fibres, Sharpey's fibres, which penetrate deep into the outer cortical bone tissue. It is absent from articular surfaces, and from the points of insertion of tendons and ligaments (entheses) (see Fig. 5.46). The periosteum is highly active during fetal development, when it generates osteoblasts for the appositional growth of bone. These cells form a layer, two to three cells deep, between the fibrous periosteum and new woven bone matrix. Osteoprogenitor cells within the mature periosteum are indistinguishable morphologically from fibroblasts. Periosteum is important in the repair of fractures: where it is absent, e.g. within the joint capsule of the femoral neck, fractures are slow to heal.
In resting adult bone, quiescent osteoblasts and osteoprogenitor cells are present chiefly on the endosteal surfaces, which act as the principal reservoir of new bone-forming cells for remodelling or repair. The endosteum provides a surface of approximately 7.5 m², thought to be important in calcium homeostasis. It is formed by flattened osteoblast precursor cells and reticular (type III collagen) fibres, and lines all the internal cavities of bone, including the Haversian canals. It overlies the endosteal circumferential lamellae, and encloses the medullary cavity.
NEUROVASCULAR SUPPLY OF BONE

Vascular supply and lymphatic drainage

The osseous circulation supplies bone tissue, marrow, perichondrium, epiphysial cartilages in young bones, and, in part, articular cartilages. The vascular supply of a long bone depends on several points of inflow which feed complex and regionally variable sinusoidal networks within the bone. The sinusoids drain to venous channels which leave through all surfaces that are not covered by articular cartilage. The flow of blood through cortical bone in the shafts of long bones is mainly centrifugal (Fig. 5.20).

Fig. 5.20 The main features of the blood supply of a long bone. Note the contrasting supplies of the diaphysis, metaphysis and epiphysis, and their connections with periosteal, endosteal, muscular and periarticular vessels. The expansion shows part of the diaphysis in more detail. The marrow cavity contains a large central venous sinus, a dense network of medullary sinusoids, and longitudinal medullary arteries and their circumferential rami. Longitudinally oblique transcortical capillaries emerge through minute ‘cornet-shaped’ foramina to become confluent with the periosteal capillaries and venules. The obliquity of the cortical capillaries is emphasized for clarity. Not to scale.
One or two main diaphysial nutrient arteries enter the shaft obliquely through nutrient foramina which lead into nutrient canals. Their sites of entry and angulation are almost constant and characteristically directed away from the dominant growing epiphysis. Nutrient arteries do not branch in their canals, but divide into ascending and descending branches in the medullary cavity which approach the epiphyses, dividing repeatedly into smaller helical branches close to the endosteal surface. The endosteal vessels are vulnerable during operations which involve passing metal implants into the medullary canal, e.g. intramedullary nailing for fractures. Near the epiphyses they are joined by terminal branches of numerous metaphysial and epiphysial arteries. The former are direct branches of neighbouring systemic vessels, the latter come from periarticular vascular arcades formed on non-articular bone surfaces. Numerous vascular foramina penetrate bones near their ends, often at fairly specific sites; some are occupied by arteries, but most contain thin-walled veins. Within bone, the arteries are unusual in consisting of endothelium with only a thin layer of supportive connective tissue. The epiphysial and metaphysial arterial supply is richer than the diaphysial supply.

Medullary arteries in the shaft give off centripetal branches which feed a hexagonal mesh of medullary sinusoids that drain into a wide, thin-walled central venous sinus. They also possess cortical branches which pass through endosteal canals to feed fenestrated capillaries in osteons (Haversian systems). The central sinus drains into veins which retrace the paths of nutrient arteries, sometimes piercing the shaft elsewhere as independent emissary veins. Cortical capillaries follow the pattern of Haversian canals, and are mainly longitudinal with oblique connections via Volkmann's canals (Fig. 5.17). At bone surfaces, cortical capillaries make capillary and venous connections with periosteal plexuses (Fig. 5.20). The latter are formed by arteries from neighbouring muscles which contribute vascular arcades with longitudinal links to the fibrous periosteum. From this external plexus a capillary network permeates the deeper, osteogenic periosteum. At muscular attachments, periosteal and muscular plexuses are confluent and the cortical capillaries then drain into interfascicular venules.

In addition to the centrifugal supply of cortical bone, there is an appreciable centripetal arterial flow to outer cortical zones from periosteal vessels. The large nutrient arteries of epiphyses form many intraosseous anastomoses, their branches passing towards the articular surfaces within the trabecular spaces of the bone. Near the articular cartilages these form serial anastomotic arcades (e.g. three or four in the femoral head), which give off end-arterial loops. These often pierce the thin hypochondral compact bone to enter, and sometimes traverse, the calcified zone of articular cartilage, before returning to the epiphysial venous sinusoids.

In immature long bones the supply is similar, but the epiphysis is a discrete vascular zone. Epiphysial and metaphysial arteries enter on both sides of the growth cartilage; there are few, if any, anastomoses between them. Growth cartilages probably receive a supply from both sources, and from an anastomotic collar in the adjoining periosteum. Occasionally, cartilage canals are incorporated into a growth plate. Metaphysial bone is nourished by terminal branches of metaphysial arteries and by primary nutrient arteries of the shaft which form terminal blind-ended sprouts or sinusoidal loops in the zone of advancing ossification. Young periosteum is more vascular, its vessels communicate more freely with those of the shaft than their adult counterparts, and they give off more metaphysial branches.
Large irregular bones, e.g. the scapula and innominate, receive a periosteal supply. In addition, they often have large nutrient arteries which penetrate directly into their cancellous bone: the two systems anastomose freely. Short bones receive numerous fine vessels which supply their compact and cancellous bone and medullary cavities from the periosteum. Arteries enter vertebrae close to the bases of their transverse processes. Each vertebral medullary cavity drains to two large basivertebral veins which converge to a foramen on the posterior surface of the vertebral body. Flatter cranial bones are supplied by numerous periosteal or mucoperiosteal vessels. Large thin-walled veins run tortuously in cancellous bone. Lymphatic vessels accompany periosteal plexuses but have not been convincingly demonstrated in bone.

**Innervation**

Nerves are most numerous in the articular extremities of long bones, vertebrae and larger flat bones, and in periosteum. Fine myelinated and unmyelinated axons accompany nutrient vessels into bone and marrow and lie in the perivascular spaces of Haversian canals. Bone has a complex autonomic and sensory innervation; osteoblasts possess receptors for several neuropeptides that are found in the nerves which supply bone, e.g. neuropeptide Y, calcitonin gene-related peptide, vasoactive intestinal peptide and substance P.
DEVELOPMENT AND GROWTH OF BONE

Most bones are formed by a process of endochondral ossification, in which preformed cartilage templates (models) define their initial shapes and positions, and the cartilage is replaced by bone in an ordered sequence. Bones such as those in the cranial vault are laid down within a fibrocellular mesenchymal membrane, by a process known as intramembranous ossification.

**Intramembranous ossification**

Intramembranous ossification is the direct formation of bone (membrane bone) within highly vascular sheets or ‘membranes’ of condensed primitive mesenchyme (Fig. 5.21). At centres of ossification, mesenchymal stem cells differentiate into osteoprogenitor cells which proliferate around the branches of a capillary network, forming incomplete layers of osteoblasts in contact with the primitive bone matrix. The cells are polarized because they secrete a fine mesh of collagen fibres and ground substance, osteoid, from the surface which faces away from the blood vessels. The earliest crystals appear in association with extracellular matrix vesicles produced by the osteoblasts; crystal formation subsequently extends into collagen fibrils in the surrounding matrix, producing an early labyrinth of woven bone, the primary spongiosa. As layers of calcifying matrix are added to these early trabeculae, the osteoblasts enclosed by matrix come to lie within primitive lacunae. New osteocytes retain intercellular contact by means of their fine cytoplasmic processes (dendrites) and, as these elongate, matrix condenses around them to form canaliculi.
As matrix secretion, calcification and enclosure of osteoblasts proceed, the trabeculae thicken and the intervening vascular spaces become narrower. Where bone remains trabecular, the process slows and the spaces between trabeculae become occupied by haemopoietic tissue. Where compact bone is forming, trabeculae continue to thicken and vascular spaces continue to narrow. Meanwhile the collagen fibres of the matrix, secreted on the walls of the narrowing spaces between trabeculae, become organized as parallel, longitudinal or spiral bundles, and the cells they enclose occupy concentric sequential rows. These irregular, interconnected masses of compact bone each have a central canal, and are called primary osteons (primary Haversian systems). They are later eroded, together with the intervening woven bone, and replaced by generations of mature (secondary) osteons.

While these changes are occurring, mesenchyme condenses on the outer surface to form a fibrovascular periosteum. Bone is laid down increasingly by new osteoblasts which differentiate from osteoprogenitor cells in the deeper layers of the periosteum. Modelling of the growing bone is achieved by varying rates of resorption and deposition at different sites.

**Endochondral ossification**

The hyaline cartilage model which forms during embryogenesis is a miniature template of the bone (cartilage bone) that will subsequently develop. It becomes surrounded by a condensed, vascular mesenchyme or perichondrium, which resembles the mesenchymal ‘membrane’ in which intramembranous ossification occurs. Its deeper layers contain osteoprogenitor cells.

The first appearance of a centre of primary ossification (Fig. 5.22) occurs when chondroblasts deep in the centre of the primitive shaft enlarge greatly, and their cytoplasm becomes vacuolated and accumulates glycogen. Their intervening matrix is compressed into thin, often perforated, septa. The cells degenerate and may die,
leaving enlarged and sometimes confluent lacunae (primary areolae) whose thin walls become calcified during the final stages (Fig. 5.23). Type X collagen is produced in the hypertrophic zone of cartilage. Matrix vesicles originating from chondrocytes in the proliferation zone are most evident in the intercolumnar regions, where they appear to initiate crystal formation. At the same time, cells in the deep layer of perichondrium around the centre of the cartilage model differentiate into osteoblasts and form a peripheral layer of bone. Initially, this periosteal collar, formed by intramembranous ossification within the perichondrium, is a thin-walled tube which encloses and supports the central shaft (Fig. 5.22, Fig. 5.23). As it increases in diameter it also extends towards both ends of the shaft.
Fig. 5.22  A, Section of a human fetal hand showing cartilaginous models of the carpal bones, and the primary ossification centres, which display varying stages of maturity, in the metacarpals and phalanges. Note that none of the carpal elements shows any evidence of ossification. B, Higher power view of an early primary ossification centre. The cartilage cells in the shaft have hypertrophied and this region is surrounded by a delicate tube or collar of subperiosteal bone (red).

(Photograph by Kevin Fitzpatrick on behalf of GKT School of Medicine, London.)
The periosteal collar which overlies the calcified cartilaginous walls of degenerate chondrocyte lacunae is invaded from the deep layers of the periosteum (formerly perichondrium) by osteogenic buds. These are blind-ended capillary sprouts and are accompanied by osteoprogenitor cells and osteoclasts. The latter excavate newly formed bone to reach adjacent calcified cartilage where they continue to erode the walls of primary chondrocyte lacunae (Fig. 5.24, Fig. 5.25). This process leads to their fusion into larger and irregular communicating spaces, secondary areolae, which fill with embryonic medullary tissue (vascular mesenchyme, osteoblasts and osteoclasts, haemopoietic and marrow stromal cells, etc.). Osteoblasts attach themselves to the delicate residual walls of calcified cartilage and lay down osteoid which rapidly becomes confluent, forming a continuous lining of bone. Further layers of bone are added, enclosing young osteocytes in lacunae, and narrowing the perivascular spaces. Bone deposition on the more central calcified cartilage ceases as the formation of subperiosteal bone continues.
cartilage (Fig. 5.24), remain to support the developing marrow tissues. These trabeculae soon become remodelled and replaced by more mature bone or by marrow. Meanwhile new, adjacent, cartilaginous regions undergo similar changes. Since these are most advanced centrally, and the epiphyses remain cartilaginous, the intermediate zones exhibit a temporospatial sequence of changes when viewed in longitudinal section (Fig. 5.26F). This region of dynamic change from cartilage to bone persists until longitudinal growth of the bone ceases.

**Fig. 5.26** The stages of endochondral ossification in a long bone.

Expansion of the cartilaginous extremity (usually an epiphysis) keeps pace with the growth of the rest of the bone both by appositional and interstitial growth. The growth zone expands in all dimensions. Growth in thickness of a developing long bone is caused by occasional transverse mitoses in its chondrocytes, and by appositional growth as a result of matrix deposition by cells from the perichondrial collar or ring at this level. The future growth plate therefore expands in concert with the shaft and adjacent future epiphysis. A zone of relatively quiescent chondrocytes (the resting zone) lies on the side of the plate closest to the epiphysis. An actively mitotic zone of cells faces towards the shaft of the bone: the more frequent divisions in the long axis of the bone soon create numerous longitudinal columns (palisades) of disc-shaped chondrocytes, each in a flattened lacuna (Fig. 5.26). Proliferation and column formation occurs in this zone of cartilage growth (the proliferative zone), and its continued longitudinal interstitial expansion provides the basic mode of elongation of a bone.
The columns of cells show increasing maturity towards the centre of the shaft, as their chondrocytes increase in size and accumulate glycogen. In the hypertrophic zone, energy metabolism is depressed at the level of the mineralizing front (Fig. 5.24). The lacunae are now separated by transverse and longitudinal walls, and the latter are impregnated with apatite crystals (the zone of calcified cartilage). The calcified partitions enter the zone of bone formation and are invaded by vascular mesenchyme containing osteoblasts, osteoclasts, etc. The partitions, especially the transverse ones, are then partly eroded while osteoid deposition, bone formation and osteocyte enclosure occur on the surfaces of the longitudinal walls. Lysis of calcified partitions is mediated by osteoclast (chondroclast) action, aided by cells associated with the terminal buds of vascular sinusoids which occupy, and come into close contact with, each incomplete columnar trabecular framework.

Continuing cell division in the growth zone adds to the epiphysial ends of cell columns, and the bone grows in length as this sequence of changes proceeds away from the diaphysial centre. The bone also grows in diameter as further subperiosteal bone deposition occurs near the epiphyses, and its medullary cavity enlarges transversely and longitudinally. Internal erosion and remodelling of the newly formed bone tissue continues.

Growth continues in this way for many months or years in different bones but eventually one or more secondary centres of ossification usually appear in the cartilaginous extremities. These epiphyseal centres (or the ends of bones which lack epiphyses) do not at first display cell columns. Instead, isogenous cell groups hypertrophy, with matrix calcification, and are then invaded by osteogenic vascular mesenchyme, sometimes from cartilage canals. Bone is formed on calcified cartilage, as described above. As an epiphysis enlarges, its cartilaginous periphery also forms a zone of proliferation in which cell columns are organized radially; hypertrophy, calcification, erosion and ossification occur at increasing depths from the surface. The early osseous epiphysis is thus surrounded by a superficial growth cartilage, and the growth plate adjacent to the metaphysis soon becomes the most active region.

As a bone reaches maturity, epiphysial and metaphysial ossification processes gradually encroach upon the growth plate from either side, eventually meeting when bony fusion of the epiphysis occurs and longitudinal growth of the bone ceases. The events which take place during fusion are broadly as follows. As growth ceases, the cartilaginous plate becomes quiescent and gradually thins, proliferation, palisading and hypertrophy of chondrocytes stop, and the cells form short, irregular conical masses. Patchy calcification is accompanied by resorption of calcified cartilage and some of the adjacent metaphysial bone, to form resorption channels which are invaded by vascular mesenchyme. Some endothelial sprouts pierce the thin plate of cartilage, and the metaphysial and epiphysial vessels unite. Ossification around these vessels spreads into the intervening zones and results in fusion of epiphysis and metaphysis.

This bone is visible in radiographs as a radiodense epiphysial line (a term which is also used to describe the level of the perichondrial collar or ring around the growth cartilage of immature bones, or the surface junction between epiphysis and metaphysis in a mature bone). In smaller epiphyses, which unite earlier, there is usually one initial eccentric area of fusion, and thinning of the residual cartilaginous plate. The original sites of fusion are subsequently resorbed and replaced by new
bone. Medullary tissue extends into the whole cartilaginous plate until union is complete and no epiphyseal ‘scar’ persists. In larger epiphyses, which unite later, similar processes also involve multiple perforations in growth plates, and islands of epiphyseal bone often persist as epiphyseal scars. Calcified cartilage coated by bone forms the epiphyseal scar, and is also found below articular cartilage. It has been called metaplastic bone, a term also applied to sites of attachments of tendons, ligaments and other dense connective tissues to bone.

The cartilaginous surfaces of epiphyses that form synovial joints remain unossified, but the typical sequence of cartilaginous zones persists in them throughout life. A similar developmental sequence occurs at synchondroses, except that the proliferative rates of chondrocytes and the replacement of cartilage by bone are similar, although not identical, on either side of the synchondrosis.

**Postnatal growth and maintenance**

Modelling, by which is meant changes in general shape, occurs in all growing bones. The process has been studied mainly in cranial and long bones with expanded extremities. A bone such as the parietal thickens and expands during growth, but decreases in curvature. Accretion continues at its edges by proliferation of osteoprogenitor cells at sutures, and periosteal bone is mainly added externally and eroded internally, but not at uniform rates or at all times. The rate of formation increases with radial distance from the centre of ossification (in this case, the future parietal eminence), and formation may also occur endocranially as well as ectocranially, changing the curvature of the bone. As the skull bones thicken and grow at the sutures, the relative positions of the original centres of ossification change in three dimensions as the vault of the skull expands with growth of the brain. The development of diploë (trabeculae of spongy bone) and marrow space internally produces outer and inner cortical plates.

Long bones elongate mainly by extension of endochondral ossification into calcified zones of adjacent growth cartilages, which are continually replaced by the longitudinal interstitial growth of their proliferative zones, with minor additions by radial epiphyseal growth. Simultaneously, diametric increases of growth cartilages and shafts occur by continuing subperiosteal deposition and endosteal erosion. However, in many bones growth occurs at different rates, and is even reversed, at different places. A bone which is initially tubular may thus become triangular in section, e.g. the tibia. Similarly, the waisted contours of metaphyses are preserved by differential rates of periosteal erosion and endosteal deposition, as metaphyseal bone becomes diaphysial in position. The junction between a field of resorption and one of deposition on the surface of a bone during its growth is called a surface reversal line. The relative position of such a line may remain stable over long periods of cortical drift.

Lamellar bone forms at variable rates which reflect the slow turnover of osteons throughout adult life. A resorption canal (cutting cone) is typically 2 mm long and takes 1–3 months to form; a new osteon (closing cone) forms in a similar period (Fig. 5.19). Internal remodelling continuously supplies young osteones with labile calcium reserves, and provides a malleable bony architecture that is responsive to changing patterns of stress. The remodelling unit in cancellous bone, equivalent to the secondary osteon of compact bone, is the bone structural unit: it has an average thickness of 40–70 µm and an average length of 100 µm, but may be more extensive and irregular in shape.
The normal development and maintenance of bone requires adequate intake and absorption of calcium, phosphorus, vitamins A, C and D, and a balance between growth hormone (GH, somatotropin), thyroid hormones, oestrogens and androgens. Various other factors, including different prostaglandins and glucocorticoids, may also play important roles in the maintenance and turnover of bone. Prolonged deficiency of calcium causes loss of bone mineral via a loss of bone tissue (osteoporosis) and consequent bone fragility. Vitamin D influences intestinal transport of calcium and phosphate, and therefore affects circulatory calcium levels. In adults, prolonged deficiency (with or without low intake) produces bones which contain regions of deformable, uncalcified osteoid (osteomalacia). During growth, similar deficiencies lead to severe disturbance of growth cartilages and ossification, e.g. reductions of regular columnar organization in growth plates, and failure of cartilage calcification even though chondrocytes proliferate. Growth plates also become thicker and less regular than normal, as exemplified in classic rickets or juvenile osteomalacia. In rickets, the uncalcified or poorly calcified cartilage trabeculae are only partially eroded: osteoblasts secrete layers of osteoid, but these fail to ossify in the metaphysial region, and ultimately gravity deforms these softened bones.

Vitamin C is essential for the adequate synthesis of collagen and matrix proteoglycans in connective tissues. When vitamin C is deficient, growth plates become thin, ossification almost stops, and metaphysial trabeculae and cortical bone are reduced in thickness. This causes fragility and delayed healing of fractures. Vitamin A is necessary for normal growth, and for a correct balance of deposition and removal of bone. Deficiency retards growth as a result of the failure of internal erosion and remodelling, particularly in the cranial base. Foramina are narrowed, sometimes causing pressure atrophy of contained nerves, and the cranial cavity and spinal canal may fail to expand with the central nervous system, which impairs nervous function. Conversely, excess vitamin A stimulates vascular erosion of growth cartilages, which become thin or totally lost, and longitudinal growth ceases. Retinoic acid, a vitamin A derivative, is involved in pattern formation in limb buds (see Ch. 51), and in the differentiation of osteoblasts.

Balanced endocrine functions are also essential to normal bone maturation, and disturbances in this balance may have profound effects. In addition to its role in calcium metabolism, excess parathyroid hormone (primary hyperparathyroidism) stimulates unchecked osteoclastic erosion of bone, particularly subperiosteally and later endosteally (osteitis fibrosa cystica). Growth hormone is required for normal interstitial proliferation in growth cartilages, and hence increase in stature. Termination of normal growth is imperfectly understood, but may involve a fall in hormone production or in the sensitivity of chondroblasts to insulin-like growth factors regulated by GH. Reduction of GH production in the young leads to quiescence and thinning of growth plates and hence pituitary dwarfism. Conversely, continued hypersecretion in the immature leads to gigantism, and in the adult results in thickening of bones by subperiosteal deposition; the mandible, hands and feet are the most affected, a condition known as acromegaly.

While continued longitudinal growth of bones depends on adequate levels of GH, effective remodelling to achieve a mature shape also requires the action of the thyroid hormones. Moreover, growth and skeletal maturity are closely related to endocrine activities of the ovaries, testes and suprarenal cortices. High oestrogen levels increase deposition of endosteal and trabecular bone, conversely, osteoporosis in
postmenopausal women reflects reduced ovarian function. Fluctuations in the rate of growth and the timing of skeletal maturation are a function of circulating levels of suprarenal and testicular androgens. In hypogonadism, growth plate fusion is delayed and the limbs therefore elongate excessively, conversely, in hypergonadism, premature fusion of the epiphyses results in diminished stature.

Although the morphogenetic factors that determine the shape of a bone have yet to be fully defined, responses to strain are believed to play a major role. Bone resorption typically occurs when gravitational or other mechanical stresses are reduced, as occurs in bed rest, or in zero gravity conditions in space. Bone subjected to constant pressure also tends to resorb, a response that underpins much orthodontic treatment, since teeth can be made to migrate slowly through alveolar bone by the application of steady lateral or medial pressure. Conversely, with constant tension, bone is deposited, e.g. the bones in the racket arm of tennis players are more robust than in the contralateral limb.

**Growth of individual bones**

Ossification centres appear over a long period during bone growth, many in embryonic life, some in prenatal life, and others well into the postnatal growing period. Ossification centres are initially microscopic but soon become macroscopic, which means that their growth can then be followed by radiological and other scanning techniques.

Some bones, including carpal, tarsal, lacrimal, nasal, and zygomatic bones, inferior nasal conchae and auditory ossicles, ossify from a single centre which may appear between the eighth intrauterine week and the tenth year, a wide sequence for studying growth or estimating age. Most bones ossify from several centres, one of which appears in the centre of the future bone in late embryonic or early fetal life (seventh week to fourth month). Ossification progresses from the centres towards the ends, which are still cartilaginous at birth (Fig. 5.27). These terminal regions ossify from separate centres, which are sometimes multiple, and which appear between birth and the late teens: they are therefore secondary to the earlier primary centre from which much of the bone ossifies. This is the pattern in long bones, as well as in some shorter bones such as the metacarpals and metatarsals, and in the ribs and clavicles.
A, Radiograph of a neonatal arm. Ossification from primary centres is well advanced in all of the limb bones except the carpals, which are still wholly cartilaginous. The gaps by which individual elements appear to be separated are filled by radiolucent hyaline cartilage, in which epiphyseal or carpal ossification will subsequently occur. Note the flaring contours, narrow midshaft and relatively expanded metaphyses of the long bones, and the proportions of the limb segments, in particular the relatively large hand, which are characteristic of this age.

B, The bones and cartilages of a neonatal left arm. Compare the radiolucent areas in the radiograph (A) with the preserved cartilaginous epiphyses and carpal elements in this specimen.

(Part B prepared by Michael C.E. Hutchinson; photographed by Kevin Fitzpatrick on behalf of GKT School of Medicine, London.)

At birth a bone such as the tibia is typically ossified throughout its diaphysis from a primary centre which appears in the seventh intrauterine week, whereas its cartilaginous epiphyses ossify from secondary centres. As the epiphyses enlarge almost all the cartilage is replaced by bone, except for a specialized layer of articular hyaline cartilage which persists at the joint surface, and a thicker zone between the diaphysis and epiphysis. Persistence of this epiphyseal plate or disc (growth plate or growth cartilage) allows increase in bone length until the usual dimensions are reached, by which time the epiphyseal plate has ossified. The bone has then reached maturity. Coalescence of the epiphysis and diaphysis is fusion, the amalgamation of separate osseous units into one.

Many long bones have epiphyses at both their proximal and distal extremities. Metacarpals, metatarsals and phalanges have only one epiphysis. Typical ribs have epiphyses for the head and articular tubercle and one for the non-articular area. The costal cartilages represent the unossified hyaline cartilage of the developing rib and therefore do not display epiphyses. Epiphyseal ossification is sometimes complex, e.g. the proximal end of the humerus is wholly cartilaginous at birth, and subsequently develops three centres during childhood which coalesce into a single mass before they fuse with the diaphysis; only one of these centres forms an articular surface, the others form the greater and lesser tubercles which give muscular attachments. Similar composite epiphyses occur at the distal end of the humerus and in the femur, ribs and vertebrae.

Many cranial bones ossify from multiple centres. The sphenoid, temporal and occipital bones are almost certainly composites of multiple elements in their evolutionary history. Some show evidence of fusion between membrane and cartilage bones which unite during growth.

If the growth rate was uniform, ossification centres would appear in a strict descending order of bone size. However, disparate rates of ossification occur at different sites and do not appear to be related to bone size. The appearance of primary centres for bones of such different sizes as the phalanges and femora are separated by, at most,
a week of embryonic life. Those for carpal and tarsal bones show some correlation
between size and order of ossification, from largest (calcaneus in the fifth fetal month)
to smallest (pisiform in the ninth to twelfth postnatal year). In individual bones,
succession of centres is related to the volume of bone which each centre produces.
The largest epiphyses, e.g. the adjacent ends of the femur and tibia, are the earliest to
begin to ossify (immediately before or after birth, and of forensic interest). At
epiphysial plates, the rate of growth is initially equal at both ends of those bones
which possess two epiphyses. However, experimental observations in other species
have revealed that one generally grows faster than the other after birth. Since the
faster-growing end also usually fuses later with the diaphysis, its contribution to length
is greater. Though faster rate has not been measured directly in human bones, later
fusion has been documented radiologically.

The more active end of a long limb bone is often termed the growing end, but this is a
misnomer. The rate of increase in stature, which is rapid in infancy and again at
puberty, demonstrates that rates of growth at epiphyses vary. The spurt at puberty, or
slightly before, decreases as epiphyses fuse in post-adolescent years, and has been
the subject of much study.

Growth cartilages do not grow uniformly at all points, which presumably accounts for
changes such as the alteration in angle between the humeral shaft and its neck. The
junctions between epiphysis and diaphysis at growth plates are not uniformly flat on
either surface. Osseous surfaces usually become reciprocally curved by differential
growth, and the epiphysis forms a shallow cup over the convex end of the shaft, with
cartilage intervening, an arrangement that may resist shearing forces at this relatively
weak region. Reciprocity of bone surfaces is augmented by small nodules and ridges,
as can be seen when the surfaces are stripped of cartilage. These adaptations
emphasize the formation of many immature bones from several elements held
together by epiphysial cartilages. Most human bones exhibit these complex junctions,
at which bone is bonded to bone through cartilage throughout the active years of
childhood and adolescence.

Forces at growth cartilages are largely compressive, but with an element of shear.
Interference with epiphysial growth may occur as a result of trauma, but more
frequently follows disease: the resulting changes in trabecular patterns of bone are
visible radiographically as dense transverse lines of arrested growth (Harris's growth
lines). Several such lines may appear in the limb bones of children afflicted by
successive illnesses.

Variation in skeletal development occurs between individuals, sexes and possibly also
races. The timing rather than the sequence of events varies, and females antedate
males in all groups studied: differences which are perhaps insignificant before birth
may be as great as two years in adolescence.
JOINTS

Joints are the regions of the skeleton where two or more bones meet and articulate. These junctions are supported by a variety of soft tissue structures and their prime functions are either to facilitate growth or to transmit forces between bones, thereby enabling movement to occur or weight to be transferred. The simplest classifications of joints relate to either the range of movement possible or the nature of the intervening soft tissues: there is no satisfactory single classification. Free movement occurs at synovial joints, whereas restricted movement occurs at joints that are sometimes referred to as synarthroses. The latter are commonly subdivided into fibrous and cartilaginous joints, according to the principal type of intervening connective tissue. What follows are descriptions of the general characteristics of each type of joint. Features that are specific to individual joints are discussed in the relevant topographical chapters.

FIBROUS JOINTS

Fibrous joints lack intervening cartilage between the two bones, the articulation is therefore fixed and movement is very restricted. The three most definable types of fibrous articulation are sutures, gomphoses and syndesmoses (Fig. 5.28).
Suture

Sutures are restricted to the skull (see Ch. 26 for descriptions of individual sutures). In a suture, the two bones are separated by a layer of membrane-derived connective tissue. The sutural aspect of each bone is covered by a layer of osteogenic cells (cambial layer) overlaid by a capsular lamella of fibrous tissue which is continuous with the periosteum on both the endo- and ectocranial surfaces. The area between the capsular coverings contains loose fibrous connective tissue and decreases with age so that the osteogenic surfaces become apposed. On completion of growth, many sutures synostose and are obliterated. Synostosis occurs normally as the skull ages: it can begin in the early twenties and continues into advanced age. A schindylesis is a specialized suture in which a ridged bone fits into a groove on a neighboring element, e.g. where the cleft between the alae of the vomer receives the rostrum of the sphenoid.

Gomphosis

A gomphosis is a peg-and-socket junction between a tooth and its socket, where the two components are maintained in intimate contact by the collagen of the periodontium connecting the dental cement to the alveolar bone. Strictly speaking, a gomphosis is not an articulation between two skeletal structures.

Syndesmosis

A syndesmosis is a truly fibrous connection between bones. It may be represented by an interosseous ligament (inferior tibiofibular joint), a slender fibrous cord, or a more dense aponeurotic membrane (posterior part of sacroiliac joint).
CARTILAGINOUS JOINTS

Cartilaginous joints may be classified as primary (synchondrosis) or secondary (symphysis), depending upon the nature of the intervening cartilage. While the distinction between fibrous and cartilaginous joints is usually clear, some degree of admixture can occur in which either a predominantly fibrous articulation contains occasional islands of cartilage or a predominantly cartilaginous articulation contains aligned dense bundles of collagen. These joints tend to be less rigid than the fibrous articulations and some permit movement, albeit restricted in range (Fig. 5.29, Fig. 5.30).

**Fig. 5.29** Examples of varieties of cartilaginous joints (see also Fig. 5.30). **A**, Sectional view of the principal tissues involved, more detailed architecture and main growth patterns of symmetrical and asymmetrical synchondroses. Lesser degrees of asymmetry occur in some locations. Synostosis is the normal fate of almost all synchondroses when endochondral growth has ceased. **B**, Intervertebral symphyses (presacral), shown in section, displaying age-related changes. Partial or complete synostosis is the normal fate of sacral and coccygeal symphyses.
Primary cartilaginous joints

Primary cartilaginous joints or synchondroses occur where advancing centres of ossification are separated by an area of hyaline (non-articular) cartilage. They are present in all postcranial bones that form from more than one centre of ossification. Since hyaline cartilage retains the capability to ossify with age, synchondroses tend to synostose when growth is complete. Primary cartilaginous joints are almost exclusively associated with growth plates (see above); the detailed anatomy of specific joints is described in the appropriate topographical chapter. The location and growth of the sphenoid-occipital synchondrosis is discussed in Chapter 26.

Secondary cartilaginous joints
Secondary cartilaginous joints or symphyses are largely defined by the presence of an intervening pad or disc of fibrocartilage interposed between the articular hyaline cartilage that covers the ends of two bones. The pad or disc varies from a few millimetres to over a centimetre in width, and the whole region is generally bound by strong, tightly adherent, dense connective tissues. Collagenous ligaments extend from the periostea of the articulating bones across the symphysis and blend with the hyaline and fibrocartilaginous perichondria: they do not form a complete capsule and contain plexuses of afferent nerve terminals which also penetrate the periphery of the fibrocartilage. The combined strength of the ligaments and of the hyaline and fibrocartilage exceeds that of the associated bones, and is designed to withstand a range of stresses (compression, tension, shear and torsion). The range of movement in a symphysis is limited by the physical nature of the articulation and also by the restrictions imposed by other bones associated with the complex. Tears are usually the result of sudden, massive stresses that occur when the body is in an inappropriate posture.

All symphyses occur in the midline (mandibular, manubriosternal, pubic and intervertebral). All except the mandibular symphysis occur in the postcranial skeleton and resist synostosis. The mandibular symphysis (symphysis menti) is histologically different from the other symphyses, however, the widespread use of this descriptive term ensures that it remains, albeit probably inappropriately, within this category.

The concept that synchondroses are temporary and concerned with growth, whereas symphyses are permanent and concerned with movement, is an oversimplification and only partly correct. Both types of joint are concerned with strength and the ability to withstand and transmit considerable stresses, both are sites at which growth occurs, and both contribute either directly or indirectly to the total movement patterns of the parts involved. The strength and mechanical properties of cartilaginous joints are acknowledged, perhaps less attention is paid to the fact that the rigidity of synchondroses also increases the efficiency of positive movements at related syndesmoses, symphyses and particularly at synovial joints. The movements that occur at a symphysis are not simple extrapolations based on the mechanical properties of a fibrocartilaginous pad or disc. For example, movement of a vertebra relative to its neighbours is a three-dimensional summation of the events that occur in all of the relevant intervertebral joints (syndesmoses, synovial joints, symphyses), each of which is subject to a particular array of stresses.

The prominent role of synchondroses in skeletal growth is widely recognized, whereas growth of symphyses has received less attention. Symphysial growth may, for convenience, be considered from two interrelated aspects, namely intrinsic growth of the fibrocartilaginous disc, and growth of the hyaline cartilaginous plates into which endochondral ossification progresses.
SYNOVIAL JOINTS

Synovial articulations are quite readily differentiated from both fibrous and cartilaginous joints (Fig. 5.31). Although the bones involved are linked by a fibrous capsule (which usually has intrinsic ligamentous thickenings), and often by internal or external accessory ligaments, the articulating bony surfaces are generally not in direct continuity. They are covered by hyaline articular cartilage of varying thickness and precise topology; contact is strictly limited between these cartilaginous surfaces, which have a very low coefficient of friction, facilitating free movement. Smooth movement of the opposing articular surfaces is aided by a viscous synovial fluid, which acts as a lubricant, but is also concerned with cellular maintenance in the articular cartilages. The production of synovial fluid requires the presence of a synovial membrane which is one of the defining characteristics of the joint type.

Fig. 5.31 Synovial joints, some main structural features and one elementary type of classification: A, simple; B, compound; C, complex joints. For clarity, the articular surfaces are artificially separated. A and C are purely diagrammatic and not related to particular joints. B, however, is a simplified representation of some features of an elbow joint; the complicated contours due to the olecranon, coronoid and radial fossae and profiles of articular fat pads have been omitted for clarity.

Articular surfaces

Articular surfaces are mostly formed by a specialization of hyaline cartilage, reflecting their preformation as parts of cartilaginous models in embryonic life. Exceptionally, surfaces of the sternoclavicular and acromioclavicular joints and both temporomandibular surfaces are covered by dense fibrous tissue which contains isolated groups of chondrocytes and little surrounding matrix – perhaps a legacy of their formation by intramembranous ossification. Articular cartilage has a wear-resistant, low-frictional, lubricated surface, which is slightly compressible and elastic and is thus ideally constructed for easy movement. It is also able to resist and distribute large forces of compression and shear generated by movement, body weight transfer and muscle contractions.

The thickness of articular cartilage may reach 5–7 mm in larger joints of young individuals but may be reduced to 1–2 mm in the elderly. Young cartilages are typically white, smooth, glistening and compressible, whereas ageing cartilages are thinner, less cellular, firmer and more brittle, with a less regular surface and a
Articular cartilages are moulded to bone (see Fig. 5.4), and variations in thickness often accentuate subjacent osseous surface shape. Typically, convex surfaces are thickest centrally, thinning peripherally, and concave surfaces are the reverse. The precise configuration, degree of congruence in various positions, and the dispositions of the surrounding capsule and ligaments, are all related to the types and ranges of movement permitted at a joint. Articular cartilage has no penetrating nerves or blood vessels (except occasional vascular loops). Its nutrition and maintenance therefore largely depend on diffusion from a peripheral vascular plexus in the synovial membrane (circulus vasculosus articuli), blood vessels in adjacent marrow spaces and synovial fluid: the relative importance of these contributions is uncertain.

The zone of articular cartilage next to the joint cavity is mainly a layer of collagen fibres arranged in various planes with small, oval chondrocytes lying deep to it in the matrix. Transmission electron microscopy of heavy metal stained preparations shows an interrupted electron-dense surface coat of a particulate or filamentous material, generally 0.03–0.1 µm thick, covering the cartilage. Synovial fluid and membranous debris, the product of chondrocytic necrosis, may contribute to this surface coat, which is transient in nature; the stable, permanent, articular surface is bounded by the most superficial collagen fibres. The ‘lamina splendens’, a structure that appears as a bright line at the free surface of articular cartilage when oblique sections are examined by negative phase contrast microscopy, is an artefact arising at the border between regions of different refractive index: it is not an anatomically distinct surface layer. The deeper zones of articular cartilage contain a highly complex, three-dimensional reticulum of interconnected fibrils, which have obvious functional implications.

With advancing age, undulations of articular surfaces deepen and develop minute, ragged projections, perhaps as a consequence of wear and tear. These changes are extremely slow in healthy joints: erosion occurs in pathologically ‘dry’ joints and where synovial fluid viscosity is altered. Mitosis is not observed in adult articular chondrocytes.

**Fibrous capsule**

A fibrous capsule completely encloses a joint except where it is interrupted by synovial protrusions (see descriptions of individual joints for specific details). It is composed of interlacing bundles of parallel fibres of white collagen and is attached continuously round the ends of the articulating bones. In small bones this attachment is usually near the periphery of the articular surfaces, but in long bones it varies considerably, and part or all of the attachment may be a significant distance from the articular surface. The capsule is perforated by vessels and nerves and may contain apertures through which synovial membrane protrudes as bursae. It is lined by a synovial membrane that also covers all non-articular surfaces (non-articular osseous surfaces, tendons and ligaments) that lie partly or wholly within the fibrous capsule, e.g. at the shoulder and knee. Where a tendon is attached inside a joint, an extension of synovial membrane usually accompanies it beyond the capsule. Some extracapsular tendons are separated from the capsule by a synovial bursa continuous with the interior of the joint. These protrusions are potential routes for the spread of infection into joints.

A fibrous capsule usually exhibits local thickenings of parallel bundles of collagen
fibres, called capsular (intrinsic) ligaments, that are named by their attachments. Some capsules are reinforced or replaced by tendons of nearby muscles or expansions from them. Accessory ligaments are separate from capsules and may be extracapsular or intracapsular in position.

All ligaments, although yielding little to tension, are pliant. They are slightly elastic and protected from excessive tension by reflex contraction of appropriate muscles. They are taut at the normal limit of a particular movement but do not resist normal actions, since they are designed to check excessive or abnormal movements.

**Synovial membrane**

Synovial membrane lines fibrous capsules and covers exposed osseous surfaces, intracapsular ligaments, bursae and tendon sheaths (Fig. 5.32). It does not cover intra-articular discs or menisci and stops at the margins of articular cartilages in a transitional zone that occupies the peripheral few millimetres of the cartilage. Synovial membrane secretes and absorbs a fluid that lubricates the movement between the articulating surfaces.

Pink, smooth and shining, the internal synovial surface displays a few small synovial villi that increase in size and number with age. Folds and fringes of membrane may also project into a joint cavity; some are sufficiently constant to be named, e.g. the alar folds and ligamentum mucosum of the knee. Synovial villi are more numerous near articular margins and on the surfaces of folds and fringes, and become prominent in some pathological states.

Accumulations of adipose tissue (articular fat pads) occur in the synovial membrane in many joints. These pads, folds and fringes are flexible, elastic and deformable cushions that occupy the potential spaces and irregularities in joints that are not wholly filled by synovial fluid. During movement they accommodate to the changing shape and volume of the irregularities, they also increase synovial area and may promote the distribution of lubricant over articular surfaces (cf. intra-articular discs and menisci).

Synovial membrane is composed of a cellular intima resting on a fibrovascular subintimal layer (subsynovial tissue). The intima consists of pleomorphic synovial cells embedded in a granular, amorphous, fibre-free extracellular matrix. There is considerable regional variation in cell morphology and numbers. Human synovial cells are generally elliptical, and have numerous cytoplasmic processes. At least two morphologically distinct populations, type A and type B synovial cells, are responsible for synthesizing some of the components of the synovial fluid.

Type A cells are macrophage-like cells characterized by surface ruffles or lamellipodia, plasma membrane invaginations and associated pinocytotic vesicles, a prominent Golgi apparatus but little rough endoplasmic reticulum. Type B synovial cells, which predominate, resemble fibroblasts and have abundant rough endoplasmic reticulum but fewer vacuoles and vesicles, and have a less ruffled plasma membrane. It is thought that some of the hyaluronan and glycoproteins of synovial fluid are synthesized by synovial type B cells, whereas the fluid component is a transudate from synovial capillaries. Type A synovial cells synthesize and release lytic enzymes and phagocytose joint debris: potential damage to joint tissues is limited by the
secretion of enzyme inhibitors by type B synovial cells. Synovial cells do not divide actively in normal synovial membranes, but their division rate increases dramatically in response to acute trauma and haemarthrosis. In such conditions the type B synovial cells divide in situ, while the type A cell population is increased by immigration of bone marrow-derived precursors.

The synovial cells of normal human joints form an interlacing, discontinuous layer, one to three cells and 20–40 µm deep, between the subintima and the joint cavity. They are not separated from the subintima by a basal lamina, and are distinguished from the subintimal cells only because they associate to form a superficial layer. In many locations, but particularly over loose subintimal tissue, areas are commonly found that are free from synovial cells. Over fibrous subintimal tissue the synovial cells may be flattened and closely packed, forming endothelioid sheets. Neighbouring cells are often separated by distinct gaps but their processes may interdigitate where they lie closer together.

The subintima is often composed of loose, irregular connective tissue, but also contains organized lamellae of collagen and elastin fibres lying parallel to the membrane surface, interspersed with occasional fibroblasts, macrophages, mast cells and fat cells. The elastic component may prevent formation of redundant folds during joint movement. Subintimal adipose cells form compact lobules surrounded by highly vascular fibroelastic interlobular septa that provide firmness, deformability and elastic recoil. The subintima merges with the synovial membrane where it covers the adjacent capsule, intracapsular ligament or tendon.

Synovial fluid

Synovial fluid occupies synovial joints, bursae and tendon sheaths. In synovial joints it is clear or pale yellow, viscous, slightly alkaline at rest (the pH lowers during activity), and contains a small mixed population of cells and metachromatic amorphous particles. Fluid volume is low: usually less than 0.5 ml can be aspirated from a large joint such as the knee.

The composition of synovial fluid is consistent with it being mainly a dialysate of blood plasma. It contains protein (approximately 0.9 mg/100 ml) derived from the blood. It also contains hyaluronan, which is thought to be a significant determinant of the viscoelastic and thixotropic (flow rate dependent) properties of synovial fluid. A small proportion (approximately 2%) of synovial protein differs from plasma protein and is probably produced by synovial type B cells, and a very small proportion (approximately 0.5%) of synovial protein appears to be a specialized lubricating glycoprotein. Synovial fluid contains a few cells (approximately 60 per ml in resting human joints), including monocytes, lymphocytes, macrophages, synovial intimal cells and polymorphonuclear leukocytes: higher counts are found in young individuals. The amorphous metachromatic particles and fragments of cells and fibrous tissue found in synovial fluid are presumed to be produced by wear and tear.

Intra-articular menisci, discs and fat pads

An articular disc or meniscus occurs between articular surfaces where congruity is low. It consists of fibrocartilage where the fibrous element usually predominates, and is not covered by synovial membrane. The term meniscus should be reserved for
incomplete discs, like those in the knee joint and, occasionally, in the acromioclavicular joint. Complete discs, such as those in the sternoclavicular and inferior radio-ulnar joints, extend across a synovial joint, dividing it structurally into two synovial cavities; they often have small perforations. The disc in the temporomandibular joint may be complete or incomplete.

The main part of a disc is relatively acellular, but the surface may be covered by an incomplete stratum of flat cells, continuous at the periphery with adjacent synovial membrane. Discs are usually connected to their fibrous capsule by vascularized connective tissue, so that they become invaded by vessels and afferent and vasomotor sympathetic nerves. Sometimes the union between disc and capsule is closer and stronger, as occurs in the knee and temporomandibular joints.

The function of intra-articular fibrocartilages is uncertain. Deductions have been made from structural or phylogenetic data, aided by mechanical analogies; suggestions include shock absorption, improvement of fit between surfaces, facilitation of combined movements, checking of translation at joints such as the knee, deployment of weight over larger surface areas, protection of articular margins, facilitation of rolling movements, and spread of lubricant. The temporomandibular disc has attracted particular attention because of its exceptional, perhaps unique, design and biomechanical properties (see Ch. 31).

The functions of labra and fat pads, two other quite common types of intra-articular structure, are also uncertain. A labrum is a fibrocartilaginous annular lip, usually triangular in cross-section, attached to an articular margin (e.g. glenoid fossa and acetabulum). It deepens the socket and increases the area of contact between articulating surfaces, and may act as a lubricant spreader. Like menisci, labra may reduce the synovial space to capillary dimensions, thus limiting drag, but unlike menisci, labra are not compressed between articular surfaces. Small fibrous labra (connective tissue rims) have been described along the ventral or dorsal margins of the zygapophysial joints at lumbar levels, as have meniscus-shaped fibroadipose meniscoids at the superior or inferior poles of the same joints. Fat pads are soft and change shape to fill joint recesses that vary in dimension according to joint position.

**Neurovascular supply**

**Vascular supply and lymphatic drainage**

Joints receive blood from periarticular arterial plexuses whose numerous branches pierce the fibrous capsules to form subsynovial vascular plexuses. Some synovial vessels end near articular margins in an anastomotic fringe, the circulus articularis vasculosus. A lymphatic plexus in the synovial subintima drains along blood vessels to the regional deep lymph nodes.

**Innervation**

A movable joint is innervated by articular branches of the nerves that supply the muscles acting on the joint and that also supply the skin covering the joint (Hilton's law). Although there is overlap between the territories of different nerves, each nerve innervates a specific part of the capsule. The region made taut by muscular contraction is usually innervated by nerves that supply the antagonists. For example, stretching the portion of the capsule of the hip joint supplied by the obturator nerve
during abduction elicits reflex contraction of the adductors that is usually sufficient to prevent damage.

Myelinated axons in articular nerves innervate Ruffini endings, lamellated articular corpuscles and structures resembling Golgi tendon organs. Ruffini endings respond to stretch and adapt slowly, whereas lamellated corpuscles respond to rapid movement and vibration and adapt rapidly; both types of receptor register the speed and direction of movement. Golgi tendon organs, innervated by the largest myelinated axons (10–15 µm diameter), are slow to adapt; they mediate position sense and are concerned in stereognosis, i.e. recognition of shape of held objects. Simple endings are numerous at the attachments of capsules and ligaments, and are thought to be the terminals of unmyelinated and thinly myelinated nociceptive axons.

Many unmyelinated postganglionic sympathetic axons terminate near vascular smooth muscle, and are presumably either vasomotor or vaso sensory. The nerve endings in synovial membrane are believed to supply blood vessels exclusively, from which it is inferred that synovial membrane is relatively insensitive to pain.

**Classification**

Synovial joints may be classified (Fig. 5.33) according to their shape. While this has some practical value, it should be remembered that they are merely variations, sometimes extreme, of two basic forms. Articular surfaces are never truly flat, or complete spheres, cylinders, cones or ellipsoids. They are better described as parts of a single ovoid surface or a complex construction of more than one such surface.
Plane joints

Plane joints are appositions of almost flat surfaces, e.g. intermetatarsal and some intercarpal joints. Slight curvature although usual, is often disregarded, and movements are considered to be pure translations or sliding between bones, whereas, in precise dynamics, even slight curvatures cannot be ignored.

Hinge joints

These joints resemble hinges because movement is largely restricted to one plane, which means that they are uniaxial, e.g. interphalangeal and humero-ulnar joints. However, the surfaces of these biological hinges differ from regular mechanical cylinders because their profiles are not arcs but varyingly spiral, which means that motion does not truly occur about a single axis. Hinge joints possess strong collateral ligaments.

Pivot joints

These are uniaxial joints in which an osseous pivot in an osteoligamentous ring allows rotation only around the axis of the pivot. Pivots may rotate in rings, e.g. the head of the radius rotates within the anular ligament and ulnar radial notch, or rings may rotate around pivots, e.g. the atlas rotates around the dens of the axis.

Bicondylar joints

Bicondylar joints are predominantly uniaxial, with a main movement in one plane, but with limited rotation about a second axis orthogonal to the first. Bicondylar joints are so named because they are formed of two convex condyles (knuckles) which
articulate with concave or flat surfaces (sometimes inappropriately also called condyles). The condyles may lie within a common fibrous capsule, e.g. the knee, or in separate capsules that necessarily cooperate in all movements as a condylar pair, e.g. temporomandibular joints.

Ellipsoid joints

Ellipsoid joints are biaxial, and consist of an oval, convex surface apposed to an elliptical concavity, e.g. radiocarpal and metacarpophalangeal joints. Primary movements occur around two orthogonal axes, e.g. flexion–extension, abduction–adduction, that may be combined as circumduction. Rotation around the third axis is largely prevented by general articular shape.

Saddle joints

Saddle joints are biaxial and have concavoconvex surfaces. Each is maximally convex in a particular direction, and is maximally concave at right angles to this direction. The convexity of the larger surface is apposed to the concavity of the smaller surface and vice versa. Primary movements occur in two orthogonal planes, but articular shape causes axial rotation of the moving bone. Such coupled rotation is never independent, and is functionally significant in habitual positioning and limitation of movement. The most familiar saddle joint is the carpometacarpal joint of the thumb, other examples include the ankle and calcaneocuboid joints.

Ball-and-socket joints

These joints are multiaxial and are formed by the reception of a globoid ‘head’ into an opposing cup, e.g. the hip and shoulder joints. Their surfaces, although resembling parts of spheres, are not strictly spherical but slightly ovoid, and consequently congruence is not perfect in most positions. Indeed, it occurs in only one position, at the end of the commonest movement.

Factors influencing movement

Movements at synovial joints depend upon a number of factors including the complexity and number of articulating surfaces and the number and position of the principal axes of movement.

Complexity of form

Most synovial joints have two surfaces and are simple articulations, e.g. the glenohumeral and interphalangeal joints. In some, one surface is wholly convex and greater in area than its opposing concave surface, and occasionally, both surfaces are concavoconvex. A joint with more than two articular surfaces is called a compound joint, e.g. the knee and the elbow. In all compound joints, articulating territories remain distinct. A synovial joint that contains an intra-articular disc or meniscus is called a complex joint, e.g. the tibiofemoral joint of the knee, the sternoclavicular and temporomandibular joints (see Fig. 5.31).

Degrees of freedom

Joint motion can be described by rotation and translation about three orthogonal axes.
There are three possible rotations (axial, abduction–adduction, flexion–extension) and three possible translations (proximo-distal, mediolateral, anteroposterior). Each is a degree of freedom. For most joints, translations are negligible and do not need consideration (Fig. 5.34). A few joints have minor pure translatory movements, but most joint motion is by rotation.

![Fig. 5.34](image)

**Fig. 5.34** The shoulder joint is multiaxial, and possesses three degrees of freedom. A–C show the three mutually perpendicular axes around which the principal movements of flexion–extension (A), abduction–adduction (B) and medial and lateral rotation (C) occur. Note that these axes are referred to the plane of the scapula and not to the coronal and sagittal planes of the erect body. Although an infinite variety of additional movements may occur at such a joint, e.g. movements involving intermediate planes or combinations, they can always be resolved mathematically into components related to the three axes illustrated.

When movement is practically limited to rotation about one axis, e.g. the elbow, a joint is termed uniaxial and has one degree of freedom. If independent movements can occur around two axes, e.g. the knee (flexion–extension and axial rotation), the joint is biaxial, and has two degrees of freedom. Since there are three axes for independent rotation, joints may have up to three degrees of freedom. This apparently simple classification is complicated by the complexity of joint structure, and has consequent effects on motion. Even though a true ‘ball and socket’ joint can rotate about many chosen axes, i.e. it is multiaxial, for each position there is a maximum of three orthogonal planes, which means that it can have, as a maximum, three degrees of freedom.

For a uniaxial hinge joint with a single degree of freedom, a single unchanging axis of rotation would be predicted. However, because the shapes of joint surfaces are complex, there is a variable radius of curvature (Fig. 5.35) and consequently the axis of rotation will vary as joint movement progresses. When the variation is minor, e.g. the elbow, it is often appropriate to describe a mean position for the axis. In others, e.g. the knee, the situation is more complex.
Simple movements are rarely such. Often motion in one direction is linked to motion in another in an obligatory fashion. There are two varieties of rotation: conjunct (coupled), which is an integral and inevitable accompaniment of the main movement, and adjunct, which can occur independently and may or may not accompany the principal movement.

Articular movements and mechanisms

Joint surfaces move by translation (gliding) and angulation (rotation), usually in combination, to produce gross movements at the joint. Where movement is slight, the reciprocal surfaces are of similar size; where it is wide, the habitually more mobile
bone has the larger articular surface.

**Translation**

Translation is the simplest motion and involves gliding or sliding without appreciable angulation. Although frequently combined with other movements, it is often considered the only motion permitted in some carpal and tarsal articulations. However, cineradiography reveals that considerable angulation occurs during movements of the small carpal and tarsal bones.

**Angulation**

Angulation implies a change in angle between the topographical axes of articulating bones, e.g. flexion and extension; abduction and adduction. Angulation can be subdivided as follows.

**Flexion**

Flexion is a widely used term, but difficult to define. It often means approximation of two ventral surfaces around a transverse axis. However, the thumb is almost at right angles to the fingers: its ‘dorsal’ surface faces laterally so that flexion and extension at its joints occur around anteroposterior axes. At the shoulder, flexion is referred to an oblique axis through the centre of the humeral head in the plane of the scapular body, the arm moving anteromedially forwards and hence nearer to the ventral aspect of the trunk. At the hip, which has a transverse axis, flexion brings the morphologically dorsal (but topographically ventral) surface of the thigh to the ventral aspect of the trunk. Description of flexion at the ankle joint is complicated by the fact that the foot is set at a right angle to the leg. Elevation diminishes this angle and is usually termed flexion: since it is the approximation of two dorsal surfaces it might equally be called extension. Flexion has also been defined as the fetal posture, implying that elevation of the foot is flexion, a view supported by withdrawal reflexes in which elevation is always associated with flexion at the knee and hip. Definitions based on morphological and physiological considerations are thus contradictory: to avoid confusion, dorsiflexion and plantarflexion are used to describe ankle movements.

**Abduction and adduction**

Abduction and adduction occur around anteroposterior axes except at the first carpometacarpal and shoulder joints. The terms generally imply lateral or medial angulation, except in digits, where arbitrary planes are chosen (midlines of the middle digit of the hand and second digit of the foot), because these are least mobile in this respect. Abduction of the thumb occurs around a transverse axis and away from the palm. Similarly, abduction of the humerus on the scapula occurs in the scapular plane around an oblique axis at right angles to it.

**Axial rotation**

Axial rotation is a widely, but often imprecisely, used term. Its restricted sense denotes movement around some notional ‘longitudinal’ axis which may even be in a separate bone, e.g. the dens of the second cervical vertebra, on which the atlas rotates. An axis may be approximately the centre of the shaft of a long bone, e.g. in medial and lateral humeral rotation (Fig. 5.34). It may be at an angle to the topographical axis of a
bone, e.g. in movement of the radius on the ulna in pronation and supination, where
the axis joins the centre of the radial head to the base of the ulnar styloid process, or
in medial and lateral femoral rotation, where the axis joins the centre of the femoral
head to a (disputed) point in the distal femur. In these examples, rotations can be
independent adjunct motions, constituting a degree of freedom, or conjunct (coupled)
rotations, which always accompany some other main movement as a consequence of
articular geometry. Obligatory conjunct (coupled) motion is frequently combined with a
degree of voluntary adjunct motion, the latter dictating what proportion of the motion
occurs above the minimum obligatory component.

Circumduction

Circumduction combines successive flexion, abduction, extension and adduction, and
occurs when the distal end of a long bone circumscribes the base of a cone that has
its apex at the joint in question, e.g. shoulder and hip joints.
DEVELOPMENT OF JOINTS

The development of joints is described in the context of limb development in Chapter 51.
Most cells possess cytoskeletal elements that are capable of lengthening or shortening and so enable the cell to change its shape. This capacity is important in a variety of cellular functions, e.g. locomotion, phagocytosis, mitosis and extension of processes. Proteins referred to as molecular motors (see Ch. 1) can effect changes of length much more rapidly than systems that are dependent on polymerization–depolymerization mechanisms (actin, tubulin), by using energy from the hydrolysis of adenosine 5'-triphosphate (ATP). Of these ATP-dependent systems, one of the most widespread is based on the interaction of actin and myosin.

In muscle cells the filaments of actin and myosin and their associated proteins are so abundant that they almost fill the interior of the cell. Moreover they align predominantly in one direction, so that interactions at the molecular level are translated into linear contraction of the whole cell. The ability of these specialized cells to change shape has thus become their most important property. Assemblies of contractile muscle cells, the muscles, are machines for converting chemical energy into mechanical work. The forces generated move limbs, inflate the lungs, pump blood, close and open tubes, etc. In man, muscle tissue constitutes 40–50% of the body mass.

CLASSIFICATION OF MUSCLE

Muscle cells (fibres) are also known as myocytes (the prefixes myo- and sarco- are frequently used in naming structures associated with muscle). They differentiate along one of three main pathways to form skeletal, cardiac or smooth muscle. Both skeletal and cardiac muscle may be called striated muscle, because their myosin and actin filaments are organized into regular, repeating elements which give the cells a finely cross-striated appearance when they are viewed microscopically. Smooth muscle, in contrast, lacks such repeating elements and thus has no striations.

Other contractile cells, including myofibroblasts and myoepithelial cells, are different in character and developmental origin. They contain smooth muscle-like contractile proteins and are found singly or in small groups.

Striated muscle

Skeletal muscle

Skeletal muscle forms the bulk of the muscular tissue of the body and consists of parallel bundles of long, multinucleate fibres. This type of muscle is capable of powerful contractions (about 100 watts per kilogram) because of the regular organization of its contractile proteins. However, the price paid for this organization is a limited contractile range: wherever a larger range of
movement is required, it is achieved through the amplification provided by the lever systems of the skeleton to which the muscle is attached (hence the name skeletal muscle) (see below).

Skeletal muscle is innervated by somatic motor nerves. It is sometimes referred to as voluntary muscle, because the movements in which it participates are often initiated under conscious control. However, this is a misleading term: skeletal muscle is involved in many movements, such as breathing, blinking, swallowing, and the actions of the muscles of the perineum and in the middle ear, which are usually or exclusively driven at an unconscious level.

**Cardiac muscle**

Cardiac muscle is found only in the heart, and in the walls of large veins where they enter the heart. It consists of a branching network of individual cells that are linked electrically and mechanically to function as a unit. Compared with skeletal muscle, cardiac muscle is much less powerful (3–5 watts per kilogram) but far more resistant to fatigue. It is provided with a continuous supply of energy by numerous blood vessels around the fibres, and abundant mitochondria within them. Cardiac muscle differs structurally and functionally from skeletal muscle in some important respects. It is, for example, intrinsically capable of rhythmic contraction, with a rate and strength which is nevertheless responsive to hormonal and autonomic nervous control.

Cardiac muscle is considered in detail in Chapter 6.

**Smooth muscle**

Smooth muscle is found in all systems of the body, in the walls of the viscera, including most of the gastrointestinal, respiratory, urinary and reproductive tracts, in the tunica media of blood vessels, in the dermis (as the arrector pili muscles), in the intrinsic muscles of the eye, and the dartos muscular layer of the scrotum. In some places, smooth muscle fasciculi are associated with those of skeletal muscle, e.g. the sphincters of the anus and the urinary bladder, the tarsal muscles of the upper and lower eyelids, the suspensory muscle of the duodenum, a transitional zone in the oesophagus, and fasciae and ligaments on the pelvic aspect of the pelvic diaphragm.

Smooth muscle contains actin and myosin, but they are not organized into repeating units, and its microscopic appearance is therefore unstriated (smooth). The elongated cells are smaller than those of striated muscle, and taper at the ends. They are capable of slow but sustained contractions, and although this type of muscle is less powerful than striated muscle, the amount of shortening can be much greater. These functional attributes are
well illustrated by its role in the walls of tubes and sacs, where its action regulates the size of the enclosed lumen and, in some cases, the consequent movement of luminal contents.

A smooth muscle cell may be excited in several ways, most commonly by an autonomic nerve fibre, a blood-borne neurohormone, or conduction from a neighbouring smooth muscle cell. Since none of these routes is under conscious control, smooth muscle is sometimes referred to as involuntary muscle.

Smooth muscle is considered in detail in Chapter 6.
SKELETAL MUSCLE

Shape and fibre architecture

It is possible to classify muscles based on their general shape and the predominant orientation of their fibres relative to the direction of pull (Fig. 5.36). Muscles with fibres that are largely parallel to the line of pull vary in form from flat, short and quadrilateral (e.g. thyrohyoid) to long and strap-like (e.g. sternohyoid, sartorius). In such muscles, individual fibres may run for the entire length of the muscle, or over shorter segments when there are transverse, tendinous intersections at intervals (e.g. rectus abdominis). In a fusiform muscle, the fibres may be close to parallel in the 'belly', but converge to a tendon at one or both ends. Where fibres are oblique to the line of pull, muscles may be triangular (e.g. temporalis, adductor longus) or pennate (feather-like) in construction. The latter vary in complexity from unipennate (e.g. flexor pollicis longus) and bipennate (e.g. rectus femoris, dorsal interossei) to multipennate (e.g. deltoid). Fibres may pass obliquely between deep and superficial aponeuroses, in a type of 'unipennate' form (e.g. soleus), or muscle fibres may start from the walls of osteofascial compartments and converge obliquely on a central tendon in circumpennate fashion (e.g. tibialis anterior). Muscles may exhibit a spiral or twisted arrangement (e.g. sternocostal fibres of pectoralis major and latissimus dorsi, which undergo a 180° twist between their medial and lateral attachments), or may spiral around a bone (e.g. supinator, which winds obliquely around the proximal radial shaft), or may contain two or more planes of fibres arranged in differing directions, a type of spiral sometimes referred to as cruciate (sternocleidomastoid, masseter and adductor magnus are all partially spiral and cruciate). Many muscles display more than one of these major types of arrangement, and show regional variations which correspond to contrasting, and in some cases independent, actions.
Muscle nomenclature

The names given to individual muscles are usually descriptive, based on their shape, size, number of heads or bellies, position, depth, attachments, or actions. The meanings of some of the terms used are given in Table 5.1.

Table 5.1 -- Terms used in naming muscles.

These terms are often used in combination, e.g. flexor digitorum longus (long flexor of the digits), latissimus dorsi (broadest muscle of the back). The functional roles implied by names should be interpreted with caution: the names given to individual muscles or muscle groups are often oversimplified, and terms denoting action may emphasize only one of a number of usual actions. Moreover, a given muscle may play different roles in different movements, and these roles may change if the movements are assisted or opposed by gravity.

**Microstructure of skeletal muscle**

The cellular units of skeletal muscle are enormous multinucleate muscle fibres (Fig. 5.37, Fig. 5.38) which develop by fusion of individual myoblasts (see below). Individual muscle fibres are long, cylindrical structures that tend to be consistent in size within a given muscle, but in different muscles may range from 10 to 100 µm in diameter and from millimetres to many centimeters in length. The cytoplasm of each fibre, sarcoplasm, is surrounded by a plasma membrane that is often called the sarcolemma. The contractile machinery is concentrated into myofibrils, long narrow structures (1–2 µm in diameter) that extend the length of the fibre and form the bulk of the sarcoplasm. Numerous moderately euchromatic, oval nuclei usually occupy a thin transparent rim of sarcoplasm between the myofibrils and the sarcolemma, and are especially numerous in the region of the neuromuscular junction (see Fig. 3.37). A transverse section of a muscle fibre may only reveal one or two nuclei, but there may be several hundred along the length of an entire fibre. Myogenic satellite cells lie between the sarcolemma and the surrounding basal lamina (see below).
Fig. 5.37 - Skeletal muscle fibres from human lateral rectus in longitudinal section, showing transverse striations representing the sarcomere organization of actin and myosin filaments. The variation in fibre diameter is typical of extraocular muscles. Capillaries (C) and nerves (N) lie between the fibres, oriented mainly in parallel and so are also sectioned longitudinally. Toluidine blue stained resin section.

(Provided by courtesy of the Department of Optometry and Visual Science, City University, London.)
The myofibrils are too tightly packed to be visible by routine light microscopy (see below). Of greater significance are transverse striations, produced by the alignment across the fibre of repeating elements, the sarcomeres, within neighbouring myofibrils. These cross-striations are usually evident in conventionally stained histological sections, but may be demonstrated more effectively using special stains. They are even more striking under polarized light when they appear as a pattern of alternating dark and light bands. The darker, anisotropic or A-bands, are birefringent and rotate the plane of polarized light strongly. The lighter, isotropic or I-bands, rotate the plane of polarized light to a negligible degree. In transverse section, the profiles of the fibres are usually polygonal (Fig. 5.38; see Fig. 5.40). The sarcoplasm often has a stippled appearance, because the transversely sectioned myofibrils are resolved as dots. Their packing density varies. In some muscles, e.g. the extrinsic muscles of the larynx, the
muscle fibres tend not to be tightly packed, whereas in others, e.g. the group of jaw closing muscles, the fibres are closely packed and have rounded profiles.

Fig. 5.40  The electron microscopic appearance of skeletal muscle in longitudinal section. A, Low-power view of parts of two adjacent muscle fibres, separated by endomysium (E) containing capillaries (C) and a peripherally-placed nucleus (N) in the fibre on the right. Mitochondria (arrows) are situated peripherally and between myofibrils (M). Myofibrils pack the cytoplasm, with their sarcomeres (contractile units) in register, as seen by the alignment of Z discs (dark transverse lines) across each muscle fibre. B, A sarcomere within a myofibril, and parts of two others. (A sarcomere is the distance between adjacent Z discs). Also seen are the A band, bisected by the M line, and I band, which here is almost obliterated in the contracted state (see Fig. 5.41). A triad is visible between myofibrils, comprised of a T-tubule (long arrow) and two terminal cisternae of sarcoplasmic reticulum (short arrows).

*Part A provided by courtesy of Professor Hans Hoppeler, Institute of Anatomy, University of Bern, Switzerland.*

In general, skeletal muscle fibres are large (there are a few exceptions, e.g. the intrinsic muscles of the larynx). This means that electron micrographs, unless of very low magnification, seldom show more than part of the interior of a fibre. Myofibrils, cylindrical structures about 1 µm diameter (Fig. 5.37), are the dominant ultrastructural feature of such micrographs. In longitudinal sections they appear as ribbons and are interrupted at regular intervals by thin, very densely stained transverse lines, which correspond to discsin the parent cylindrical structure. These are the Z-lines or, more properly, Z-discs (Zwischenscheiben = interval discs) that divide the myofibril into a linear series of repeating contractile units, sarcomeres, each of which is typically 2.2 µm long in resting muscle. At higher power, sarcomeres are seen to consist of two types of filament, thick and thin, organized into regular arrays (Fig. 5.38; Fig. 5.40). The thick filaments, which are approximately 15 nm in diameter, are composed mainly of myosin. The thin filaments, which are 8 nm in diameter, are composed mainly of actin. The arrays of thick and thin filaments form a partially overlapping structure in
which electron density (as seen in the electron microscope) varies according to the amount of protein present. The A-band consists of the thick filaments, together with lengths of thin filaments that interdigitate with, and thus overlap, the thick filaments at either end (Fig. 5.40, Fig. 5.41). The central, paler region of the A-band, which is not penetrated by the thin filaments, is called the H-zone (Helle = light). At their centres, the thick filaments are linked together transversely by material that constitutes the M-line (Mittelscheibe = middle [of] disc), that is visible in most muscles. The I-band consists of the adjacent portions of two neighbouring sarcomeres in which the thin filaments are not overlapped by thick filaments. The thin filaments of adjacent sarcomeres are anchored in the Z-disc, which bisects the I-band. A third type of filament is composed of the elastic protein, titin.
Fig. 5.41 Sarcomeric structures. The drawings below the electron micrograph (of two myofibrils sectioned longitudinally and with their long axes, orientated transversely) indicate the corresponding arrangements of thick and thin filaments. Relaxed and contracted states are shown to illustrate the changes which occur during shortening. Insets at the top show the electron micrographic appearance of transverse sections through the myofibril at the levels shown. Note that the packing geometry of the thin filaments changes from a square array at the Z-disc to a hexagonal array where they interdigitate with thick filaments in the A-band.

(Photographs by Professor Brenda Russell, Department of Physiology and Biophysics, University of Illinois at Chicago.)

The high degree of organization of the arrays of filaments is equally evident in electron micrographs of transverse sections (Fig. 5.41, Fig. 5.42). The thick myosin filaments form a hexagonal lattice. In the regions where they overlap the thin filaments, each myosin filament is surrounded by six actin filaments at the trigonal points of the lattice. In the I-band, the thin filament pattern changes from hexagonal to square as the filaments approach the Z-disc, where they are incorporated into a square lattice structure.
The banded appearance of individual myofibrils is a function of the regular alternation of the thick and thin filament arrays. The size of myofibrils places them at the limit of resolution of light microscopy: cross-striations are only visible at that level because of the alignment in register of the bands in adjacent myofibrils across the width of the whole muscle fibre. In suitably stained relaxed material, the A-, I- and H-bands are quite distinct, whereas the Z-discs, which are such a prominent feature of electron micrographs, are thin and much less conspicuous in the light microscope, and M-lines cannot be resolved.

Muscle proteins

Myosin, the protein of the thick filament, constitutes 60% of the total myofibrillar protein and is the most abundant contractile protein. The thick filaments of skeletal and cardiac muscle are 1.5 µm long. Their composition from myosin heavy and light chain assemblies is described in Chapter 1. The other components of myosin, the regulatory proteins tropomyosin and troponin, play a major part in the control of contraction. Actin is the next most abundant contractile protein and constitutes 20% of the total myofibrillar protein. In its filamentous form, F-actin, it is the principal protein of the thin filaments. A number of congenital myopathies result from gene mutations in components of the thin filament assembly (reviewed in Clarkson et al 2004). The third type of long sarcomeric filament connects the thick filaments to the Z-disc, and is formed by the giant protein, titin, which has a molecular mass in the millions. Single titin molecules span the half-sarcomere between the M-lines and the Z-discs, into which they are inserted. They have a tethered portion in the A-band, where they are attached to thick filaments as far as the M-line, and an elastic portion in the I-band. The elastic properties of titin endow the relaxed muscle fibre with passive resistance to stretching and with elastic recoil.

A number of proteins which are neither contractile nor regulatory are responsible for the structural integrity of the myofibrils, particularly their regular internal arrangement. A component of the Z-disc, α-actinin, is a rod-shaped molecule which anchors the plus-ends of actin filaments from adjacent sarcomeres to the Z-disc. Nebulin inserts into the Z-disc, associated with the thin filaments, and regulates the lengths of actin filaments. An intermediate filament protein characteristic of muscle, desmin, encircles the myofibrils at the Z-disc and, with the linking molecule plectrin, forms a meshwork that connects myofibrils together within the muscle fibre and to the sarcolemma. Myomesin holds myosin filaments in their regular lattice arrangement in the region of the M line. Dystrophin is confined to the periphery of the muscle fibre, close to the cytoplasmic face of the sarcolemma. It binds to actin intracellularly and is also
associated with a large oligomeric complex of glycoproteins, the dystroglycan/sarcoglycan complex, that spans the membrane and links specifically with merosin, the α2 laminin isoform of the muscle basal lamina. This stabilizes the muscle fibre and transmits forces generated internally on contraction to the extracellular matrix.

*(Photograph by Professor Stanley Salmons, from a specimen provided by courtesy of Tim Helliwell, Department of Pathology, University of Liverpool.)*

Dystrophin is the product of the gene affected in Duchenne muscular dystrophy, a fatal disorder that develops when mutation of the gene leads to the absence of the protein. A milder form of the disease, Becker muscular dystrophy, is associated with a reduced size and/or abundance of dystrophin. Female carriers (heterozygous for the mutant gene) of Duchenne muscular dystrophy may also have mild symptoms of muscle weakness. At about 2500 kb, the gene is one of the largest yet discovered, which may account for the high mutation rate of Duchenne muscular dystrophy (approximately 35% of cases are new mutations). Other muscular dystrophies may involve deficiencies in proteins functionally associated with dystrophin, such as the dystroglycan/sarcoglycan complex or α2 laminin. The involvement in muscular
dystrophy of defects in the dystrophin adhesion complex is reviewed in Batchelor & Winder (2006).

Other sarcoplasmic structures

Although myofibrils are the dominant ultrastructural feature of skeletal muscle, the fibres contain other organelles essential for cellular function, such as ribosomes, Golgi apparatus and mitochondria. Most of them are located around the nuclei, between myofibrils and the sarcolemma and, to a lesser extent, between the myofibrils. Mitochondria, lipid droplets and glycogen provide the metabolic support needed by active muscle. The mitochondria are elongated and their cristae are closely packed. The number of mitochondria in an adult muscle fibre is not fixed, but can increase or decrease quite readily in response to sustained changes in activity. Spherical lipid droplets, approximately 0.25 µm in diameter, are distributed uniformly throughout the sarcoplasm between myofibrils. They represent a rich source of energy that can be tapped only by oxidative metabolic pathways: they are therefore more common in fibres which have a high mitochondrial content and good capillary blood supply. Small clusters of glycogen granules are dispersed between myofibrils and among the thin filaments. In brief bursts of activity they provide an important source of anaerobic energy that is not dependent on blood flow to the muscle fibre.

Tubular invaginations of the sarcolemma penetrate between the myofibrils in a transverse plane at the limit of each A-band (Fig. 5.40). The lumina of these transverse (T-) tubules are thus in continuity with the extracellular space. At the ends of the muscle fibre, where force is transmitted to adjacent connective tissue structures, the sarcolemma is folded into numerous finger-like projections that strengthen the junctional region by increasing the area of attachment.

The sarcoplasmic reticulum (SR) is a specialized form of smooth endoplasmic reticulum and forms a plexus of anastomosing membrane cisternae that fills much of the space between myofibrils (Fig. 5.43). The cisternae expand into larger sacs, junctional sarcoplasmic reticulum or terminal cisternae, where they come into close contact with T-tubules, forming structures called triads (Fig. 5.40; Fig. 5.43). The membranes of the SR contain calcium–ATPase pumps that transport calcium ions into the terminal cisternae, where the ions are bound to calsequestrin, a protein with a high affinity for calcium, in dense storage granules. In this way, calcium can be accumulated and retained in the terminal cisternae at a much higher concentration than elsewhere in the sarcoplasm. Ca^{2+}-release channels (ryanodine receptors) are concentrated mainly in the terminal cisternae and form one half of the junctional ‘feet’ or ‘pillars’ that bridge the SR and T-tubules at the triads. The other half of the junctional feet is the T-tubule receptor that constitutes the voltage sensor.
Connective tissues of muscle

The endomysium is a delicate network of connective tissue that surrounds muscle fibres, and forms their immediate external environment. It is the site of metabolic exchange between muscle and blood, and contains capillaries and bundles of small nerve fibres. Ion fluxes associated with the electrical excitation of muscle fibres take place through its proteoglycan matrix. The endomysium is continuous with more substantial septa of connective tissue that constitute the perimysium. The latter ensheathes groups of muscle fibres to form parallel bundles or fasciculi, carries larger blood vessels and nerves and accommodates neuromuscular spindles. Perimysial septa are themselves the inward extensions of a collagenous sheath, the epimysium,
which forms part of the fascia that invests whole muscle groups.

Epimysium consists mainly of type I collagen, perimysium contains type I and type III collagen, and endomysium contains collagen types III and IV. Collagen IV is associated particularly with the basal lamina that invests each muscle fibre.

The epimysial, perimysial and endomysial sheaths coalesce where the muscles connect to adjacent structures at tendons, aponeuroses, and fasciae (see below): this gives the attachments great strength, since the tensile forces are distributed in the form of shear stresses, which are more easily resisted. This principle is also seen at the ends of the muscle fibres, which divide into finger-like processes separated by insertions of tendinous collagen fibres. Although there are no desmosomal attachments at these myotendinous junctions, there are other specializations that assist in the transmission of force from the interior of the fibre to the extracellular matrix. Actin filaments from the adjacent sarcomeres, which would normally insert into a Z-disc at this point, instead penetrate a dense, subsarcolemmal filamentous matrix that provides attachment to the plasma membrane. This matrix is similar in character to the cytoplasmic face of an adherens junction. The structure as a whole is homologous to the intercalated discs of cardiac muscle. At the extracellular surface of the junctional sarcolemma, integrins provide contact with the basal lamina which in turn adheres closely to collagen and reticular fibres (type III collagen) of the adjacent tendon or other connective tissue structure.

**Vascular supply and lymphatic drainage**

In most muscles the major source artery enters on the deep surface, frequently in close association with the principal vein and nerve, which together form a neurovascular hilum. The vessels subsequently course and branch within the connective tissue framework of the muscle. The smaller arteries and arterioles ramify in the perimysial septa and give off capillaries which run in the endomysium: although the smaller vessels lie mainly parallel to the muscle fibres, they also branch and anastomose around the fibres, forming an elongated mesh.

Mathes & Nahai (1981) have classified the gross vascular anatomy of muscles into five types according to the number and relative dominance of vascular pedicles which enter the muscle (Fig. 5.44). This classification has important surgical relevance in determining which muscles will survive and therefore be useful for pedicled or free tissue transfer procedures using techniques of plastic and reconstructive surgery. Type I muscles possess a single vascular pedicle supplying the muscle belly, e.g. tensor faciae latae (supplied by the ascending branch of the lateral circumflex femoral artery) and gastrocnemius (supplied by the sural artery). Type II muscles are served by a single dominant vascular pedicle and several minor pedicles, and can be supported on a minor pedicle as well as the dominant pedicle, e.g. gracilis (supplied by the medial circumflex femoral artery in the dominant pedicle). Type III muscles are supplied by two separate dominant pedicles each from different source arteries, e.g. rectus abdominus (supplied by the superior and inferior epigastric arteries) and gluteus maximus (supplied by the superior and inferior gluteal arteries). Type IV muscles have multiple small pedicles which, in isolation, are not capable of supporting the whole muscle, e.g. sartorius and tibialis anterior: about 30% survive reduction onto a single vascular pedicle. Type V muscles have one dominant vascular pedicle and multiple secondary segmental pedicles, e.g. latissimus dorsi (supplied by the
thoracodorsal artery as the primary pedicle, and thoracolumbar perforators from the lower six intercostal arteries and the lumbar arteries as the segmental supply), and pectoralis major (supplied by the pectoral branch of the thoracoacromial axis as the dominant pedicle, and anterior perforators from the internal thoracic vessels as the segmental supply).

**Fig. 5.44** Classification of muscles according to their blood supply.
(By permission from Cormack GC, Lamberty BGH 1994 The Arterial Anatomy of Skin Flaps, 2nd edn. Edinburgh: Churchill Livingstone.)

In muscle cross-sections, the number of capillary profiles found adjacent to fibres usually varies from 0 to 3. Fibres that are involved in sustained activities, such as posture, are served by a denser capillary network than fibres that are recruited only infrequently. It is common for muscles to receive their arterial supply via more than
one route. The accessory arteries penetrate the muscle at places other than the hilum, and ramify in the same way as the principal artery, forming vascular territories. The boundaries of adjacent territories are spanned by anastomotic vessels, sometimes at constant calibre, but more commonly through reduced-calibre arteries or arterioles which are referred to as ‘choke vessels’ (see Ch. 6). These arterial arcades link the territories into a continuous network.

Veins branch in a similar way, forming venous territories that correspond closely to the arterial territories. In the zones where the arterial territories are linked by choke vessels, the venous territories are linked by anastomosing veins, in this case without change of calibre. On either side of these venous bridges, the valves in the adjacent territories direct flow in opposite directions towards their respective pedicles, but the connecting veins themselves lack valves, and therefore permit flow in either direction.

Because of the potential for relative movement within muscle groups, vessels tend not to cross between muscles, but radiate to them from more stable sites or cross at points of fusion. Where a muscle underlies the skin, vessels bridge between the two. These may be primarily cutaneous vessels, i.e. they supply the skin directly, but contribute small branches to the muscle as they pass through it, or they may be the terminal branches of intramuscular vessels which leave the muscle to supplement the cutaneous blood supply. The latter are less frequent where the muscle is mobile under the deep fascia. The correspondence between the vascular territories in the skin and underlying tissues gave rise to the concept of angiosomes, which are composite blocks of tissue supplied by named distributing arteries and drained by their companion veins (see Ch. 6).

The pressure exerted on valved intramuscular veins during muscular contraction functions as a ‘muscle pump’ that promotes venous return to the heart. In some cases this role appears to be amplified by veins which pass through the muscle after originating elsewhere in superficial or deep tissues (see Ch. 79). The extent to which the muscle capillary bed is perfused can be varied in accordance with functional demand. Arteriovenous anastomoses, through which blood can be returned directly to the venous system without traversing the capillaries, provide an alternative, regulated pathway.

The lymphatic drainage of muscles begins as lymphatic capillaries in epimysial and perimysial, but not endomysial, sheaths. These converge to form larger lymphatic vessels that accompany the veins and drain to the regional lymph nodes.

**Innervation**

Every skeletal muscle is supplied by one or more nerves. In the limbs, face and neck there is usually a single nerve, although its axons may be derived from neurons located in several spinal cord segments and their associated ganglia. Muscles such as those of the abdominal wall, which originate from several embryonic segments, are supplied by more than one nerve. In most cases, the nerve travels with the principal blood vessels within a neurovascular bundle, approaches the muscle near to its least mobile attachment, and enters the deep surface at a position which is more or less constant for each muscle.

Nerves supplying muscle are frequently referred to as ‘motor nerves’, but they contain
both motor and sensory components. The motor component is mainly composed of large, myelinated α-efferent axons, which supply the muscle fibres, supplemented by small, thinly myelinated γ-efferents, or fusimotor fibres, which innervate the intrafusal muscle fibres of neuromuscular spindles, and fine, non-myelinated autonomic efferents (C fibres), which innervate vascular smooth muscle. The sensory component consists of large, myelinated IA and smaller group II afferents from the neuromuscular spindles, large myelinated IB afferents from the Golgi tendon organs, and fine myelinated and non-myelinated axons which convey pain and other sensations from free terminals in the connective tissue sheaths of the muscle.

Within muscles, nerves travel through the epimysial and perimysial septa before entering the fine endomysial tissue around the muscle fibres. α-Motor axons branch repeatedly before they lose their myelinated sheaths and terminate in a narrow zone towards the centre of the muscle belly known as the motor point. Clinically, this is the place on a muscle from which it is easiest to elicit a contraction with stimulating electrodes. Long muscles generally have two or more terminal, or end-plate bands, because many muscle fibres do not run the full length of an anatomical muscle. The terminal branch of an α-motor axon contacts a muscle fibre at a specialized synapse, the neuromuscular junction (see Fig. 3.37). It gives off several short, tortuous branches each ending in an elliptical area, the motor end plate. The underlying discoidal patch of sarcolemma, the sole plate or subneural apparatus, is thrown into deep synaptic folds. This discrete type of neuromuscular junction is an example of an en plaque ending and is found on muscle fibres which are capable of propagating action potentials. A different type of ending is found on slow tonic muscle fibres, which do not have this capability, e.g. in the extrinsic ocular muscles, where slow tonic fibres form a minor component of the anatomical muscle. In this case the propagation of excitation is taken over by the nerve terminals, which branch over an extended distance to form a number of small neuromuscular junctions (en grappe endings). Some muscle fibres of this type receive the terminal branches of more than one motor neurone. The terminals of the γ-efferents that innervate the intrafusal muscle fibres of the neuromuscular spindle also take a variety of different forms.

The terminal branches of α-motor axons are normally in a ‘one-to-one’ relationship with their muscle fibres: a muscle fibre receives only one branch, and any one branch innervates only one muscle fibre. When a motor neurone is excited, an action potential is propagated along the axon and all of its branches to all of the muscle fibres that it supplies. The motor neurone and the muscle fibres that it innervates can therefore be regarded as a functional unit, the motor unit: the arrangement accounts for the more or less simultaneous contraction of a number of fibres within the muscle. The size of a motor unit varies considerably. In muscles used for precision tasks, e.g. extraocular muscles, interossei and intrinsic laryngeal muscles, each motor neurone innervates perhaps 10 muscle fibres, whereas in a large limb muscle, a motor neurone may innervate several hundred muscle fibres. Within a muscle, the fibres belonging to one motor unit are distributed over a wide territory, without regard to fascicular boundaries, and intermingle with the fibres of other motor units. The motor units become larger in cases of nerve damage, because denervated fibres induce collateral or terminal sprouting of the remaining axons. Each new branch can reinnervate a fibre, thus increasing the territory of its parent motor neurone.

**Muscle contraction: basic physiology**
The arrival of an action potential at the motor end plate of a neuromuscular junction causes acetylcholine (ACh) to be released from storage vesicles into the highly infolded 30–50 nm synaptic cleft that separates the nerve ending from the sarcolemma (see Fig. 3.37). ACh is rapidly bound by receptor molecules located in the junctional folds, triggering an almost instantaneous increase in the permeability, and hence conductance, of the postsynaptic membrane. This generates a local depolarization (the end-plate potential), which initiates an action potential in the surrounding sarcolemma. The activity of the neurotransmitter is rapidly terminated by the enzyme acetylcholinesterase (AChE), which is bound to the basal lamina in the sarcolemmal junctional folds. The sarcolemma is an excitable membrane, and action potentials generated at the neuromuscular junction propagate rapidly over the entire surface of the muscle fibre.

The action potentials are conducted radially into the interior of the fibre via the T-tubules, extensions of the sarcolemma (see above), ensuring that all parts of the muscle fibre are activated rapidly and almost synchronously. Excitation–contraction coupling is the process whereby an action potential triggers the release of calcium from the terminal cisternae of the sarcoplasmic reticulum into the cytosol. This activates a calcium-sensitive switch in the thin filaments (see below) and so initiates contraction. At the end of excitation, the T-tubular membrane repolarizes, calcium release ceases, calcium ions are actively transported back to the calsequestrin stores in the sarcoplasmic reticulum by the calcium–ATPase pumps, and the muscle relaxes.

The lengths of the thick and thin filaments do not change during muscle contraction. The sarcomere shortens by the sliding of thick and thin filaments past one another, which draws the Z-discs towards the middle of each sarcomere (Fig. 5.41). As the overlap increases, the I- and H-bands narrow to near extinction, while the width of the A-bands remains constant. Filament sliding depends on the making and breaking of bonds (cross-bridge cycling) between myosin head regions and actin filaments. Myosin heads ‘walk’ or ‘row’ along actin filaments using a series of short power strokes, each resulting in a relative movement of 5–10 nm. Actin filament binding sites for myosin are revealed only in the presence of calcium, which is released into the sarcoplasm from the sarcoplasmic reticulum, causing a repositioning of the troponin–tropomyosin complex on actin (the calcium-sensitive switch). Myosin head binding and release are both energy dependent (ATP binding is required for detachment of bound myosin heads as part of the normal cycle). In the absence of ATP (as occurs postmortem) the bound state is maintained, and is responsible for the muscle stiffness known as rigor mortis.

The summation of myosin power strokes leads to an average sarcomere shortening of up to 1 µm: an anatomical muscle shortens by a centimetre or more, depending on the muscle, because each muscle has thousands of sarcomeres in series along its length. For further details of actin–myosin interactions in muscle contraction, see Alberts et al (2002) and Pollard & Earnshaw (2007) (see Bibliography of selected titles for publication details).

Slow twitch vs fast twitch

The passage of a single action potential through a motor unit elicits a twitch contraction where peak force is reached within 25–100 ms, depending on the motor unit type involved. However, the motor neurone can deliver a second nervous impulse
in less time than it takes for the muscle fibres to relax. When this happens, the muscle fibres contract again, building the tension to a higher level. Because of this mechanical summation, a sequence of impulses can evoke a larger force than a single impulse and, within certain limits, the higher the impulse frequency, the more force is produced ('rate recruitment'). An alternative strategy is to recruit more motor units. In practice, the two mechanisms appear to operate in parallel, but their relative importance may depend on the size and/or function of the muscle: in large muscles with many motor units, motor unit recruitment is probably the more important mechanism.

With the exception of rare tonic fibres, skeletal muscles are composed entirely of fibres of the twitch type. These fibres can all conduct action potentials, but they differ in other respects. Some fibres obtain their energy very efficiently by aerobic oxidation of substrates, particularly of fats and fatty acids. They have large numbers of mitochondria; contain myoglobin, an oxygen-transport pigment related to haemoglobin; and are supported by a well-developed network of capillaries that maintains a steady nutrient supply of oxygen and substrates. Such fibres are well suited to functions such as postural maintenance, in which moderate forces need to be sustained for prolonged periods. At the other end of the spectrum, some fibres have few mitochondria, little myoglobin, and a sparse capillary network, and store energy as cytoplasmic glycogen granules. Their immediate energy requirements are met largely through anaerobic glycolysis, a route that provides prompt access to energy but that is less sustainable than oxidative metabolism. They are capable of brief bursts of intense activity that must be separated by extended quiescent periods during which intracellular pH and phosphate concentrations, perturbed in fatigue, are restored to normal values and glycogen and other reserves are replenished.

Different types of fibre tend to be segregated into different muscles in some animals: some muscles have a conspicuously red appearance, reflecting their rich blood supply and high myoglobin content associated with a predominantly aerobic metabolism, whereas others have a much paler appearance, reflecting a more anaerobic character. These variations in colour led to the early classification of muscle into red and white types. This classification has now been largely superseded by myosin-based typing and the presence of specific disease-related enzymes.

In man, all muscles are mixed; fibres that are specialized for aerobic working conditions intermingle with fibres of a more anaerobic or intermediate metabolic character. The different types of fibre are not readily distinguished in routine histological preparations but are clear when specialized enzyme histochemical techniques are used. On the basis of metabolic differences, individual fibres can be classified as predominantly oxidative, slow twitch (red) fibres, or glycolytic, fast twitch (white) fibres. Muscles composed mainly of oxidative, slow twitch fibres correspond to the red muscles of classical descriptions. Muscles that are predominantly oxidative in their metabolism contract and relax more slowly than muscles relying on glycolytic metabolism. This difference in contractile speed is due in part to the activation mechanism (volume density of sarcotubular system and proteins of the calcium ‘switch’ mechanism), and in part to molecular differences between the myosin heavy chains of these types of muscle. These differences affect the ATPase activity of the myosin head, which in turn alters the kinetics of its interaction with actin, and hence the rate of cross-bridge cycling. Differences between myosin isoforms may be detected histochemically: ATPase histochemistry continues to play a significant role in
diagnostic typing (Table 5.2). Two main categories have been described: type I fibres, which are slow-contracting, and type II, which are fast-contracting. Molecular analyses have revealed that type II fibres may be further subdivided according to their content of myosin heavy-chain isoforms into types IIA, IIB and IIX (Schiaffino & Reggiani 1996). There is a correlation between categories and metabolism, and therefore with fatigue resistance, such that type I fibres are generally oxidative (slow oxidative) and resistant to fatigue, type IIA are moderately oxidative, glycolytic (fast oxidative glycolytic) and fatigue resistant, and IIB largely rely on glycolytic metabolism (fast glycolytic) and so are easily fatigued.

Fibre type transformation

The fibre type proportions in a named muscle may vary between individuals of
different age or athletic ability. Fibre type grouping, where fibres with similar metabolic and contractile properties aggregate, increases after nerve damage and with age. It occurs as a result of reinnervation episodes, where denervated fibres are ‘taken over’ by a sprouting motor neurone and their type properties transformed under direction of the new motor neurone. If the nerves to fast white and slow red muscles are cut and cross-anastomosed in experimental animals, so that each muscle is reinnervated by the other’s nerve, the fast muscle becomes slower-contracting, and the slow muscle faster-contracting (Buller et al 1960). There is evidence that fibre type transformation may be a response to the patterns of impulse traffic in the nerves innervating the muscles. If fast muscles are stimulated continuously for several weeks at 10 Hz, a pattern similar to that normally experienced by slow muscles, they develop slow contractile characteristics and acquire a red appearance and a resistance to fatigue even greater than that of slow muscles.

The initial phase of slowing can be explained by less rapid cycling of calcium, the result of a reduction in the extent of the sarcoplasmic reticulum and changes in the amount and molecular type of proteins involved in calcium transport and binding. Chronic stimulation also triggers the synthesis of myosin heavy and light chain isoforms of the slow muscle type: the associated changes in cross-bridge kinetics result in a lower intrinsic speed of shortening. The muscle becomes more resistant to fatigue through changes in the metabolic pathways responsible for the generation of ATP and a reduced dependence on anaerobic glycolysis. There is a switch to oxidative pathways, particularly those involved in the breakdown of fat and fatty acids, and an associated increase in capillary density and in the fraction of the intracellular volume occupied by mitochondria. If stimulation is discontinued, the sequence of events is reversed and the muscle regains, over a period of weeks, all of its original characteristics. The reversibility of transformation is one of several lines of evidence that the changes take place within existing fibres, and not by a process of degeneration and regeneration.

Many of the changes in the protein profile of a muscle that are induced by stimulation are now known to be the result of transcriptional regulation. For example, analysis of the messenger RNA species encoding myosin heavy chain isoforms shows that expression of the fast myosin heavy chain mRNA is downregulated within a few days of the onset of chronic stimulation, while the slow myosin heavy chain mRNA is upregulated. Although myosin isoform expression is responsive to the increase in use induced by chronic stimulation, it tends to be stable under physiological conditions unless these involve a sustained departure from normal postural or locomotor behaviour.

Attachments of skeletal muscles

The forces developed by skeletal muscles are transferred to bones by connective tissue structures: tendons, aponeuroses and fasciae.

Tendons

Tendons (Fig. 5.45) take the form of cords or straps of round or oval cross-section, and consist of dense, regular connective tissue. They contain fascicles of type I collagen, orientated mainly parallel to the long axis, but are to some extent interwoven. The fasciculi may be conspicuous enough to give tendons a longitudinally
striated appearance to the unaided eye. Tendons generally have smooth surfaces, although large tendons may be ridged longitudinally by coarse fasciculi (e.g. the osseous aspect of the angulated tendon of obturator internus). Loose connective tissue between fascicles provides a conduit for small vessels and nerves, and condenses on the surface as a sheath or epitendineum, which may contain elastin and irregularly arranged collagen fibres. The loose attachments between this sheath and the surrounding tissue present little resistance to movements of the tendon, but in situations where greater freedom of movement is required, a tendon is separated from adjacent structures by a synovial sheath.

**Fig. 5.45** Attachment of a tendon (orange) to skeletal muscle (pink). The regular dense connective tissue of the tendon consists of parallel bundles of type I collagen fibres which are orientated in the long axis of the tendon and the muscle to which it is attached. A few elongated fibroblast nuclei are visible in the tendon.

Tendons are strongly attached to bones, both at the periosteum and through fasciculi (extrinsic collagen fibres). Tendinous attachments (entheses or osteotendinous junctions) have been broadly categorized as either fibrocartilagenous or fibrous. In fibrocartilagenous entheses, four zones of tissue have been identified: pure dense fibrous connective tissue (continuous with and indistinguishable from the tendon), uncalcified fibrocartilage, calcified fibrocartilage and bone (continuous with and indistinguishable from the rest of the bone). There are no sharp boundaries between the zones, and the proportions of each component vary between entheses (Fig. 5.46A,B,D). At fibrous entheses, which are characteristic of the shafts of long bones, the tendon is attached to bone by dense fibrous connective tissue either directly or indirectly via the periosteum (Fig. 5.46C). It has been suggested that the greater area of the skeleton to which many fibrous entheses (e.g. pronator teres, deltoid) are attached compared with fibrocartilagenous entheses (e.g. rotator cuff tendons) is
important in dissipating stress. (For a review of entheses and the concept of the ‘enthesis organ’, see Benjamin et al 2006.)

Tendons are slightly elastic and may be stretched by 6–10% of their length without damage. Recovery of the elastic ‘strain’ energy stored in tendons can make movement more economical. Although they resist extension, tendons are flexible and can therefore be diverted around osseous surfaces or deflected under retinacula to redirect the angle of pull. Since tendons are composed of collagen and their vascular supply is sparse, they appear white. However, their blood supply is not unimportant: small arterioles from adjacent muscle tissue pass longitudinally between the fascicles, branching and anastomosing freely, and accompanied by venae comitantes and lymphatic vessels. This longitudinal plexus is augmented by small vessels from adjacent loose connective tissue or synovial sheaths. Vessels rarely pass between bone and tendon at osseous attachments, and the junctional surfaces are usually devoid of foramina. A notable exception is the calcaneal tendon (Achilles tendon), which receives a blood supply across the osseotendinous junction. During postnatal development, tendons enlarge by interstitial growth, particularly at myotendinous junctions, where there are high concentrations of fibroblasts. Growth decreases along the tendon from the muscle to the osseous attachments. The thickness finally attained by a tendon depends on the size and strength of the associated muscle, but appears to be influenced by additional factors such as the degree of pennation of the muscle. The metabolic rate of tendons is very low but increases during infection or injury. Repair involves an initial proliferation of fibroblasts followed by interstitial deposition of new collagen fibres.

The nerve supply to tendons is largely sensory, and there is no evidence of any capacity for vasomotor control. Golgi tendon organs, specialized endings that are sensitive to force, are found near myotendinous junctions; their large myelinated afferent axons run within branches of muscular nerves or in small rami of adjacent peripheral nerves.

Form and function in skeletal muscles

Direction of action

Although muscles differ in their internal architecture, the resultant force is directed along the line of the tendon: any forces transverse to this direction must therefore be in balance (Fig. 5.36, Fig. 5.47). In strap-like muscles, the transverse component is negligible. In fusiform, bipennate and multipennate muscles, symmetry in the arrangement of the fibres produces a balanced opposition between transverse components, whereas in asymmetrical muscles, e.g. unipennate muscles, the fibres generate an unopposed lateral component of force which is balanced by intramuscular pressure.
Muscles that incorporate a twist in their geometry unwind it as they contract, so that they tend not only to approximate their attachments but also to bring them into the same plane. Muscles that spiral around a bone tend to reduce the spiral on contraction, imparting rotational force.

**Force and range of contraction**

The force developed by an active muscle is the summation of the tractive forces exerted by millions of cross-bridges as they work asynchronously in repeated cycles of attachment and detachment. This force depends on the amount of contractile machinery that is assembled in parallel, and therefore on the cross-sectional area of the muscle. The phrase ‘contractile machinery’ has been chosen deliberately here.
Mechanically, it matters little that the myofilaments are assembled into myofibrils, the myofibrils into fibres, and the fibres into fascicles (see Fig. 5.38): the total area occupied by myofilamentous arrays determines the force. If the fibres are small, the force will be influenced only to the extent that more of the cross-sectional area will be occupied by non-contractile elements, such as endomysial connective tissue. If there are many small fascicles, the amount of perimysial connective tissue in the cross-section will increase.

The range of contraction generated by an active muscle depends on the relative motion that can take place between the overlapping arrays of thick and thin filaments in each sarcomere. In vertebrate muscle, the construction of the sarcomere sets a natural limit to the amount of shortening that can take place: the difference between the minimum overlap and the maximum overlap of the thick and thin filaments represents a shortening of about 30%. Since the sarcomeres are arranged in series, the muscle fibres shorten by the same percentage. The actual movement that takes place at the ends of the fibres will depend on the number of sarcomeres in series, i.e. it will be proportional to fibre length. By way of illustration, compare the behaviour of two muscles, fixed at one end, both having fibres parallel to the line of pull and the same cross-sectional area. If one muscle is twice as long as the other, then the force developed by each muscle will be the same, but the maximum movement produced at the free ends will be twice as much for the longer muscle. Muscles in which the fibres are predominantly parallel to the line of pull are often long and thin (strap-like): they develop rather low forces, but are capable of a large range of contraction. Where greater force is required the cross-sectional area must be increased, as occurs in a pennate construction (Fig. 5.48). Here, the fibres are set at an angle to the axis of the tendon (the angle of pennation). The range of contraction produced by such a muscle will be less than that of a strap-like muscle of the same mass, because the fibres are short and a smaller fraction of the shortening takes place in the direction of the tendon. The obliquely directed force can be resolved vectorially into two components, one acting along the axis of the tendon, and one at 90° to this. In symmetrical forms (Fig. 5.48), the transverse force is balanced by fibres on the opposite side of the tendon. The functionally significant component is the one acting along the axis of the tendon. As the lengths of the vectors show, less force is available in this direction than is developed by the fibres themselves. In practice, this loss is not very great: angles of pennation are usually less than 30°, and so the force in the direction of the tendon may be 90% or more of that in the fascicles (\(\cos 30° = 0.87\)). Angulation of a set of fibres reduces both the force and range of contraction along the axis of the tendon. However, these negative consequences are outweighed by the design advantage conferred by pennation, i.e. the opportunity to extend the tendinous aponeurosis, and so increase the area available for the attachment of muscle fibres. A given mass of muscle can then be deployed as a large number of short fibres, increasing the total cross-sectional area, and hence the force, available. In a multipennate muscle, the effective cross-sectional area is larger still, and the fibres tend to be even shorter. The ‘gearing’ effect of pennation on a muscle therefore results from an internal exchange of fibre length for total fibre area: this allows much greater forces to be developed, but at the expense of a reduced range of contraction.
Although the terms power and strength are often used interchangeably with force, they are not synonymous. Power is the rate at which a muscle can perform external work and is equal to force $\times$ velocity. Since force depends on the total cross-sectional area of fibres, and velocity (the rate of shortening) depends on their length, power is related to the total mass of a muscle. Strength is usually measured on intact subjects in tasks which require the participation of several muscles, when it is as much an expression of the skillful activation and coordination of these muscles as it is a measure of the forces which they contribute individually. Thus it is possible for strength to increase without a concomitant increase in the true force-generating capacities of the muscles involved, especially during the early stages of training.
Historically, attempts were made to elucidate the actions of muscles by gross observation. The attachments were identified by dissection, and the probable action deduced from the line of pull. With the use of localized electrical stimulation it became possible to study systematically the actions of selected muscles in the living subject. This approach was pioneered above all by Duchenne de Boulogne in the mid 19th century. Such knowledge is necessarily incomplete: a study of isolated muscles, whether by dissection, postmortem or stimulation in vivo, cannot reveal the way in which those muscles behave in voluntary movements, in which several muscles may participate in a variety of synergistic and stabilizing roles. Duchenne appreciated this, and supplemented electrical stimulation with clinical observations on patients with partial paralysis to make more accurate deductions about the way in which muscles acted together in normal movement. Manual palpation can be used to detect contraction of muscles during the performance of a movement, but tends to be restricted to superficially placed muscles, with examination taking place under quasi-static conditions. Modern knowledge of muscle action has been acquired almost entirely by recording the electrical activity which accompanies mechanical contraction, a technique known as electromyography (EMG). This technique can be used to study voluntary activation of deep as well as superficial muscles, under static or dynamic conditions. Multiple channels of EMG can be used to examine coordination between the different muscles that participate in a movement. These data can be further supplemented by monitoring joint angle and ground reaction force, and by recording the movement on camera or with a three-dimensional motion analysis system.

**Actions of muscles**

Conventionally, the action of a muscle is defined as the movement that takes place when it contracts. However, this is an operational definition: equating ‘contraction’ with shortening, and ‘relaxation’ with lengthening is too simple in the context of whole muscles and real movements. Whether a muscle approximates its attachments on contraction depends on the degree to which it is activated, and the forces against which it has to act. The latter are generated by numerous factors: gravity and inertia, any external contact or impact, actively by opposing muscles, and passively by the elastic and viscous resistance of all the structures which undergo extension and deformation, some within the muscle itself, others in joints, inactive muscles and soft tissues. Depending on the conditions, an active muscle may therefore maintain its original length or shorten or lengthen, and during this time its tension may increase, decrease or not change. Movements that involve shortening of an active muscle are termed concentric, e.g. contraction of biceps/brachialis while raising a weight and flexing the elbow. Movements in which the active muscle undergoes lengthening are termed eccentric, e.g. in lowering the weight previously mentioned, biceps/brachialis ‘pays out’ length as the elbow extends. Eccentric contractions are associated with increased risk of muscle tears, especially in the hamstrings. Muscle contraction that does not involve change in muscle length is isometric.

Natural movements are accomplished by groups of muscles. Each muscle may be classified, according to its role in the movement, as a prime mover, antagonist, fixator or synergist. It is usually possible to identify one or more muscles which are consistently active in initiating and maintaining a movement: they are its prime movers. Muscles that wholly oppose the movement, or initiate and maintain the opposite movement, are antagonists, e.g. brachialis has the role of prime mover in elbow flexion, and triceps is the antagonist. To initiate a movement, a prime mover
must overcome passive and active resistance and impart an angular acceleration to a limb segment until the required angular velocity is reached; it must then maintain a level of activity sufficient to complete the movement. Antagonists may be transiently active at the beginning of a movement, and thereafter they remain electrically quiescent until the deceleration phase, when units are activated to arrest motion. During the movement, the active prime movers are not completely unrestrained, and are balanced against the passive, inertial and gravitational forces mentioned above.

When prime movers and antagonists contract together they behave as fixators, stabilizing the corresponding joint by increased transarticular compression, and creating an immobile base on which other prime movers may act, e.g. flexors and extensors of the wrist co-contract to stabilize the wrist when an object is grasped tightly in the fingers. In some cases, sufficient joint stability can be afforded by gravity, acting either on its own, e.g. knee and hip joints when they are in or near the close-packed position in the erect posture, or in conjunction with a single prime mover, e.g. the shoulder joint when it is stabilized by supraspinatus with the arm pendent. In other cases, and whenever strong external forces are encountered, prime movers and antagonists contract together, holding the joint in any required position.

Acting across a uniaxial joint, a prime mover produces a simple movement. Acting at multiaxial joints, or across more than one joint, prime movers may produce more complex movements which contain elements that have to be eliminated by contraction of other muscles. The latter assist in accomplishing the movement, and are considered to be synergists, although they may act as fixators, or even as partial antagonists of the prime mover. For example, flexion of the fingers at the interphalangeal and metacarpophalangeal joints is brought about primarily by the long flexors, superficial and deep. However, these also cross intercarpal and radiocarpal joints, and if movement at these joints was unrestrained, finger flexion would be less efficient. Synergistic contraction of the carpal extensors eliminates this movement, and even produces some carpal extension, which increases the efficiency of the desired movement at the fingers.

In the context of different movements, a given muscle may act differently, as a prime mover, antagonist, fixator or synergist. Even the same movement may involve a muscle in different ways if it is assisted or opposed by gravity. For example, in thrusting out the hand, triceps is the prime mover responsible for extending the forearm at the elbow, and the flexor antagonists are largely inactive. However, when the hand lowers a heavy object, the extensor action of the triceps is replaced by gravity, and the movement is controlled by active lengthening, i.e. eccentric contraction, of the flexors. It is important to remember that all movements take place against the background of gravity, and its influence must not be overlooked.

**Development of skeletal muscle**

Most information about the early development of the skeletal musculature in man has been derived from other vertebrate species. However, where direct comparisons with the developing human embryo have been made, the patterns and mechanisms of muscle formation have been found to be the same.

A myogenic lineage, denoted by the expression of myogenic determination factors, can be demonstrated transiently in some cells shortly after their ingestion through the
primitive streak. Skeletal muscle found throughout the body is derived from this paraxial mesenchyme, which is formed from ingress at the streak and subsequently segmented into somites (see also the origin of extraocular muscles, Ch. 41).

Skeletal muscle originates from a pool of premyoblastic cells which arise in the dermatomyotome of the maturing somite and begin to differentiate into myoblasts at 4–5 weeks of gestation. By 6 weeks, cells have migrated from the dermatomyotomal compartment to form the myotome in the centre of the somite (see Fig. 44.3). These myotomal precursor cells are identified by the expression of myogenic determination factors; they will eventually differentiate within the somite to form the axial (or epaxial) musculature (erector spinae). A distinct cohort of precursor cells migrates away from the somite to invade the lateral regions of the embryo; there they form the muscles of the limbs (see Ch. 51), limb girdles and body wall (hypaxial musculature; see Fig. 44.3). Virtually all cells in the lateral half of the newly formed somite are destined to migrate in this way. Myogenic determination factors are not expressed in these cells until the muscle masses coalesce. The appearance of myotomal myoblasts, and the migration of myoblasts to the prospective limb region, occurs first in the occipital somites. Thereafter these processes follow the general craniocaudal progression of growth, differentiation and development of the embryo. The myoblastic cells from which the limb muscles develop do not arise in situ from local limb bud mesenchyme, as was once thought, but migrate from the ventrolateral border of those somites adjacent to the early limb buds.

Myogenic determination factors

The myogenic determination factors Myf-5, myogenin, MyoD and Myf-6 (herculin) are a family of nuclear phosphoproteins. They have in common a 70-amino-acid, basic helix-loop-helix (bHLH) domain that is essential for protein–protein interactions and DNA binding. Outside the bHLH domain there are sequence differences between the factors that probably confer some functional specificity. The myogenic bHLH factors play a crucial role in myogenesis. Forced expression of any of them diverts non-muscle cells to the myogenic lineage. They activate transcription of a wide variety of muscle-specific genes by binding directly to conserved DNA sequence motifs (–CANNTG–known as E-boxes) that occur in the regulatory regions (promoters and enhancers) of these genes. Their effect may be achieved cooperatively, and can be repressed, e.g. by some proto-oncogene products. Some of the bHLH proteins can activate their own expression. Accessory regulatory factors, whose expression is induced by the bHLH factors, provide an additional tier of control.

The myogenic factors do not all appear at the same stage of myogenesis (Buckingham et al 2003). In the somites, Myf-5 is expressed early, before myotome formation, and is followed by expression of myogenin. MyoD is expressed relatively late together with the contractile protein genes. Myf-6 is expressed transiently in the myotome and becomes the major transcript postnatally. Whether this specific timing is important for muscle development is not yet clear. The creation of mutant mice deficient in the bHLH proteins (gene ‘knock-out’) has shown that myogenin is crucial for the development of functional skeletal muscle, and that while neither Myf-5 nor MyoD is essential to myogenic differentiation on their own, lack of both results in a failure to form skeletal muscle. In the limb bud (see Ch. 51) the pattern of expression of the bHLH genes is generally later than in the somite: Myf-5 is expressed first but
transiently, followed by *myogenin* and *MyoD*, and eventually *Myf-6*. These differences provide evidence at the molecular level for the existence of distinct muscle cell populations in the limb and somites. It may be that the myogenic cells that migrate to the limb differ at the outset from those that form the myotome, or their properties may diverge subsequently under the influence of local epigenetic factors.

**Formation of muscle fibres**

In both myotomes and limb buds, myogenesis proceeds in the following way. Myoblasts become spindle-shaped and begin to express muscle-specific proteins. The mononucleate myoblasts aggregate and fuse to form multinucleate cylindrical syncytia, or myotubes, in which the nuclei are aligned in a central chain (Fig. 5.49). These primary myotubes attach at each end to the tendons and developing skeleton. The initiation of fusion does not depend on the presence of nerve fibres, since these do not penetrate muscle primordia until after the formation of primary myotubes.
Fig. 5.49  Stages in formation of skeletal muscle. Mononucleate myoblasts fuse to form multinucleate primary myotubes, characterized initially by central nuclei. Subsequently, other myoblasts align along the primary myotubes and begin to fuse with one another, forming secondary myotubes. In large animals, such as man, further generations of new muscle fibres are similarly formed. As the contractile apparatus is assembled, the nuclei move to the periphery, cross-striations become visible and primitive features of the neuromuscular junction emerge. Later, small adult-type myoblasts – satellite cells – can be seen lying between the basal lamina and the sarcolemma of the mature muscle fibre. These too appear to be derived from cells that originated in the somites during early development.

(Redrawn from a figure provided by Terry Partridge, Department of Genetic Medicine, Children's National Medical Center, Washington DC.)

Although synthesis of the contractile machinery is not dependent upon fusion of myoblasts, it proceeds much more rapidly after fusion. Sarcomere formation begins at the Z-disc, which binds actin filaments constituting the I-band to form I–Z–I complexes. The myosin filaments assemble on the I–Z–I complexes to form A-bands. Nebulin and titin are among the first myofibrillar proteins to be incorporated into the sarcomere, and may well determine the length and position of the contractile filaments. Desmin intermediate filaments connect the Z-discs to the sarcolemma at an early stage, and these connections are retained.

Myogenic cells continue to migrate and to divide, and during weeks 7–9 there is extensive de novo myotube formation. Myoblasts aggregate near the midpoint of the primary myotubes and fuse with each other to form secondary myotubes, a process that may be related to early neural contact. Several of these smaller diameter myotubes may be aligned in parallel with each of the primary myotubes. Each develops a separate basal lamina and makes independent contact with the tendon. Initially, the primary myotube provides a scaffold for the longitudinal growth of the secondary myotubes, but eventually they separate. At the time of their formation, the secondary myotubes express an ‘embryonic’ isoform of the myosin heavy chains, whereas the primary myotubes express a ‘slow’ muscle isoform apparently identical to that found in adult slow muscle fibres. In both primary and secondary myotubes, sarcomere assembly begins at the periphery of the myotube and progresses inwards towards its centre. Myofibrils are added constantly and lengthen by adding sarcomeres to their ends. T-tubules are formed and grow initially in a longitudinal direction: since they contain specific proteins not found in plasma membranes, they are probably assembled via a different pathway from that which supports the growth of the sarcolemma. The sarcoplasmic reticulum wraps around the myofibrils at the level of the I-bands.

By 9 weeks, the primordia of most muscle groups are well defined, contractile proteins have been synthesized and the primitive beginnings of neuromuscular junctions can be observed, confined initially to the primary myotubes. Although some secondary fibre formation can take place in the absence of a nerve, most is initiated at sites of innervation of the primary myotubes. The pioneering axons branch and establish contact with the secondary myotubes. By 10 weeks these nerve–muscle contacts have become functional neuromuscular junctions and the muscle fibres contract in response to impulse activity in the motor nerves. Under this new influence the secondary fibres express fetal (sometimes referred to as neonatal) isoforms of the myosin heavy chains. At this stage several crucial events take place which may be dependent on, or facilitated by, contractile activity. As the myofibrils encroach on the centre of the myotube, the nuclei move to the periphery, and the characteristic morphology of the adult skeletal muscle myofibre is established. The myofibrils become aligned laterally, and A- and I-bands in register across the myotube produce
cross-striations that are visible at the light microscopic level. T-tubules change from a longitudinal to a transverse orientation and adopt their adult positions: they may be guided in this process by the sarcoplasmic reticulum, which is more strongly bound to the myofibrils.

The myotubes and myofibres are grouped into fascicles by growing connective tissue sheaths, and the fascicles are assembled to build up entire muscles. As development proceeds, the increase in intramuscular volume is accommodated by remodelling of the connective tissue matrix.

At 14–15 weeks, primary myotubes are still in the majority, but by 20 weeks the secondary myotubes predominate. During weeks 16–17, tertiary myotubes appear: they are small and adhere to the secondary myotubes, with which they share a basal lamina. They become independent by 18–23 weeks, their central nuclei move to the periphery, and they contribute a further generation of myofibres. The secondary and tertiary myofibres are always smaller and more numerous than the primary myofibres. In some large muscles, higher order generations of myotubes may be formed.

Late in fetal life, a final population of myoblasts appears which will become the satellite cells of adult muscle. These normally quiescent cells lie outside the sarcolemma beneath the basal lamina (Fig. 5.49, Fig. 5.50). M-cadherin, a cell adhesion protein of possible regulatory significance, occurs at the site of contact between a satellite cell and its muscle fibre. In a young individual, there is one satellite cell for every 5–10 muscle fibre nuclei. The latter are incapable of DNA synthesis and mitosis, and satellite cells are therefore important as the sole source of additional muscle fibre nuclei during postnatal growth of muscle (to maintain the ratio of cytoplasmic volume per nucleus as fibres increase in mass). After satellite cells divide, one of the daughter cells fuses with the growing fibre, the other remains as a satellite cell capable of further rounds of division. Similar events may take place to support exercise-induced hypertrophy of adult skeletal muscle. Satellite cells provide a reservoir of myoblasts capable of initiating regeneration of an adult muscle after damage. Other stem cell populations may also be induced to begin a myogenic differentiation pathway, e.g. bone marrow stem cells and processed lipoaspirate cells (Mizuno et al 2002).
The development of fibre types

Developing myotubes express an embryonic isoform of myosin which is subsequently replaced by fetal and adult myosin isoforms. The major isoform of sarcomeric actin in fetal skeletal muscle is cardiac α-actin; only later is this replaced by skeletal α-actin. The significance of these developmental sequences is not known.

The pattern of expression is fibre-specific as well as stage-specific. In primary myotubes, embryonic myosin is replaced by adult slow myosin from about 9 weeks onwards. In secondary and higher order myotubes the embryonic myosin isoform is superseded first by fetal and then by adult fast myosin, and a proportion go on to express adult slow myosin. Other fibre-specific, tissue-specific and species-specific patterns of myosin expression have been described in mammalian limb muscles and jaw muscles.

The origin of this diversity in the temporal patterns of expression of different fibres, even within the same muscle, is far from clear. It has been suggested that intrinsically different lineages of myoblast emerge at different stages of myogenesis or in response to different extracellular cues. If this is the case, their internal programmes may be retained or overridden when they fuse with other myoblasts or with fibres that have already formed. The fibres that emerge from this process go on to acquire a phenotype that will depend on the further influence of hormones and neural activity.

In man, unlike many smaller mammals, muscles are histologically mature at birth, but fibre type differentiation is far from complete. In postural muscles, the expression of type I myosin increases significantly over the first few years of life; during this period
the fibre type proportions in other muscles become more divergent. The presence in adult muscles of a small proportion of fibres with an apparently transitional combination of protein isoforms reinforces the view that changes in fibre type continue to some extent in all muscles and throughout adult life. Fibre type transitions also occur in relation to damage or neuromuscular disease; under these conditions, the developmental sequence of myosins may be recapitated in regenerating fibres.

**Growth and regulation of fibre length**

Muscle fibres grow in length by addition of sarcomeres to the ends of the myofibrils. It is important that the number of sarcomeres is regulated throughout life, so that the mean sarcomere length, and hence filament overlap, is optimized for maximum force. This is achieved by addition or removal of sarcomeres in response to any prolonged change of length. For example, if a limb is immobilized in a plaster cast, the fibres of muscles that have been fixed in a shortened position lose sarcomeres, while those that have been fixed in a lengthened position add sarcomeres; the reverse process occurs after the cast has been removed.

**Satellite cells and muscle repair**

Until the mid 20th century, the mechanisms responsible for the maintenance and repair of skeletal muscle were unclear. These issues were largely resolved by the almost simultaneous discovery that multinucleated muscle fibres were formed by the fusion of mononucleated precursors, myoblasts, and that a population of satellite cells, so-called because of their position on the edge of the fibre, existed between the basal lamina of the mature muscle fibre and its sarcolemma. Although satellite cells constitute 2–5% of the nuclei enclosed by the basal lamina, their role in repair and regeneration of muscle was not resolved until quite recently, because they could be identified only by their anatomical position and quiescent appearance. In contrast, active myoblasts at sites of muscle injury lose both of these features. In recent years, the discovery of a number of myogenic differentiation genes whose expression is retained in the quiescent satellite cell has elucidated their role.

Studies in mouse models, where genetic analysis is possible, have shown that the functional properties of postnatal satellite cells are dependent on the expression of the *Pax7* gene, whereas the prenatal development of muscle is not similarly dependent. This implies that the satellite cells are not simply the relics of the prenatal myogenic population although they appear to be derived from the same embryonic source in the somites. Moreover, satellite cells are not a homogeneous population: no two differentiation markers concur completely. This is also the situation in human tissue (Fig. 5.51). It has yet to be determined whether this variation reflects a difference in position in the lineage, in functional status, or in the adjacent environment.
The satellite cell been rigorously established in mice as being both necessary and sufficient for effective regeneration of damaged skeletal muscle. The cells proliferate to replace their resident region of muscle in 3–4 days and to replenish the quiescent satellite cell population (Collins & Partridge 2005). In man, there is histological evidence of the rapid accumulation of myoblasts, presumably derived from local satellite cells, at sites of muscle damage.

A point of wide pathological interest is the demonstration that the failing regenerative potency of satellite cells in aging muscle seems in large part to be attributable to age-related changes in the systemic environment rather than a decline in the intrinsic capabilities of the satellite cells themselves (Conboy et al 2005).
BIOMECHANICS

The musculoskeletal system is essentially a mechanical system, designed to support, protect and move the body, and capable of adapting to changing mechanical demands (see Benjamin & Maganaris 2006, for a review of the ways in which different elements of the musculoskeletal system respond to exercise). Structures such as long bones and synovial joints have specific mechanical functions; the material properties of the skeletal tissues from which they are derived permit optimal adaptations to diverse mechanical demands.

The purpose of this section is to explain, in a non-mathematical way, how mechanical principles shape the human musculoskeletal system. Mechanical considerations explain why bones are stiff and tendons are tough, why the surfaces of some synovial joints are imperfectly matched, and why some tendons insert closer to joints than others. The emerging subject of ‘mechanobiology’ considers how cells adapt their matrix to prevailing mechanical demands and explains why some tissues are better at doing this than others.

MECHANICAL CONCEPTS

Forces, moments and torques

A force is an action which deforms an object, or which causes it to move, and can be termed compressive, tensile or shear, according to the manner in which it deforms objects (Fig. 5.52). A force $F$ acting at the end of a lever of length $L$ will generate a bending moment ($F \times L$) acting about the pivot point of the lever. A torque or torsional moment (Fig. 5.52F) may be quantified in similar terms. The combined influence of several forces can be calculated as shown in Fig. 5.53. If the forces all act in the same direction, they may be added; if they act in different directions each force must be resolved into two imaginary components which act in two anatomically convenient directions at 90° to each other, using simple trigonometry. All components acting in the same direction are added to form two forces (S and C in Fig. 5.53) which can be used to calculate the magnitude and direction of the single resultant force (which has a similar effect to all of the individual forces combined). Forces acting on a stationary object are analysed according to the principle that all forces acting in any given direction must balance each other (i.e. add to zero) and all moments or torques acting about a given pivot point must also balance each other.
Fig. 5.52 The effects of different types of loading on a solid object (shown in A) are illustrated in B–F.
Mechanical properties of structures

Most biological structures deform readily when a sufficient force is applied to them, but their resistance to deformation increases steadily as the magnitude of the force increases: the resulting graph of force against deformation resembles the one shown in Fig. 5.54. Stiffness is the ratio of force to deformation (typical units N/mm) and so is represented by the gradient of the graph. The initial region of low stiffness, or ‘toe region’, is followed by a stiffer region in which the graph is almost linear. In many biological structures, the ‘toe region’ can be explained by the straightening out of the zig-zag ‘crimp’ structure of collagen type I fibres, whereas the linear region represents...
direct stretching of the straightened collagen fibres. If the deformed structure springs back immediately to its original dimensions when the deforming force is removed, the deformation is termed elastic; a deformation that shows no sign of recovering is plastic, and one that recovers eventually, but gradually, is viscoelastic (see below). Strength is the force at which an object becomes damaged, and is usually interpreted either as the force at which the gradient of the graph first reduces (the elastic limit) or the force when the gradient falls to zero (the ultimate strength).

**Fig. 5.54** A typical force-deformation graph for a skeletal structure subjected to mechanical loading. In the initial ‘toe region’, deformation increases rapidly with force, but this is followed by a linear region in which the deformation increases more slowly, and in proportion to the applied force. The gradient of the graph indicates the stiffness of the structure at any given load. Strength is the force at which an object becomes damaged, and this is usually interpreted either as the force at which the gradient first reduces (the elastic limit) or the force when the gradient falls to zero (the ultimate strength).

**Properties of materials**

The properties of materials must be expressed in such a way that they are independent of the size and shape of the structure they constitute. A force divided by the area over which that force is applied gives a stress value (force per unit area); the resulting deformation divided by the original length of the object gives a strain value (fractional or percentage deformation). Stress divided by strain is the size-independent material equivalent of the stiffness of an object, and is an important physical property termed the modulus. There are different types of modulus, but essentially they
correspond to stiffness, or resistance to deformation.

Energy and shock absorption

Deforming an object may require a considerable expenditure of energy. Technically, the work done (or energy expended) is proportional to the average force exerted, multiplied by the distance moved. This is mathematically equivalent to the area under the graph in Fig. 5.55. For this reason, the area is referred to as the strain energy, i.e. the energy that has been expended in deforming the object. If the object has elastic properties, it will spring back to its original shape when the deforming force is removed, and all the strain energy is then released. (This release of energy explains why a stretched rope can recoil violently if it snaps.) Structures such as coiled springs, which can resist high forces and also deform extensively, are capable of storing large amounts of energy, and so can act as shock absorbers when they are continually compressed and stretched. Tendons act in a similar manner during locomotion: they store strain energy when their muscles contract, and release most of it as the muscles relax later in the gait cycle. A small fraction of the stored strain energy, the hysteresis energy, is dissipated as heat (Fig. 5.55), and can cause generation of heat in large tendons involved in vigorous repetitive activity. Any material or structure that is capable of absorbing large amounts of strain energy before failure is termed tough; otherwise it is brittle. From Fig. 5.55 it is apparent that tough materials must be both strong and extensible: examples of strong but brittle materials are glass and tooth enamel, which both undergo minimal deformation and so display very steep force-deformation graphs.
Fig. 5.55  This force–deformation graph shows how an object deforms when a force is applied to it (upwards arrow) and how it recovers its shape when the force is gradually released (downwards arrow). The area under the loading curve represents the strain energy that has been expended in deforming the object. The area under the unloading curve represents the energy that is given up when the object is allowed to spring back to its original shape. The small area in between represents energy which cannot be recovered but is dissipated as heat. This is the hysteresis energy.

Liquids

A liquid has negligible rigidity and so deforms readily to take the shape of its container. When compressed, it maintains practically the same volume, but it flows to equalize the intensity of loading within it. As a result, a static liquid under load exhibits a single internal pressure (force per unit area) that does not vary with location or direction. Even delicate objects are not deformed when immersed in a high pressure liquid if they themselves are filled with liquid, because the internal and external pressures on them are exactly equal, which explains why cells can survive high pressures in liquids without damage to their plasma membrane. Of the musculoskeletal tissues, only the nucleus pulposus of intervertebral discs exhibits true liquid behaviour, although other tissues such as bone and cartilage contain liquid which is able to move relative to the solid matrix that surrounds it.

Viscoelasticity

Materials are said to be viscoelastic if they behave partly like a thick (viscous) fluid and partly like an elastic solid. Viscoelastic deformations change with time, even when the deforming stress is constant, and complete recovery from such deformations also takes some time after the stress is removed (Fig. 5.56). In most biological materials, viscous behaviour occurs because applied loading causes fluid to flow from the most heavily loaded regions to the least loaded, by percolating through very small (nanometre-scale) pores in the matrix, a process which can take hours: for this reason, the term poroelastic is often preferred to viscoelastic when referring to tissues such as cartilage. Creep and stress relaxation are two important manifestations of viscoelasticity. Creep may be described as continuing deformation under constant load (Fig. 5.56), whereas stress relaxation is a gradual decrease in force resisted by a viscoelastic material when it is initially deformed by a certain amount, and then held with the same constant deformation.
Fig. 5.56  The deformation of viscoelastic materials varies with time. In this example, a load is applied at zero time which causes an immediate elastic deformation, followed by a slowly increasing time-dependent deformation (creep). When the load is removed, some deformation is recovered immediately, but full recovery is achieved only slowly.
MATERIAL PROPERTIES OF SKELETAL TISSUES

The material properties of several skeletal tissues are compared in Table 5.3.

Table 5.3 -- Tensile materials properties of skeletal tissues. For comparison, alloy steel has a strength of 600 MPa and a modulus of 20,000 MPa.

Bone

Bone consists mainly of collagen type I, and microcrystals of the mineral hydroxyapatite. Collagen gives bone considerable tensile strength, and renders it very tough when fractured, whereas the mineral component gives bone a very high compressive modulus and high compressive strength. Rigidity (stiffness) is the defining characteristic of bone: it enables the tissue to provide precisely shaped surfaces in synovial joints which will deform very little under load, and it also enables fast locomotion when muscles pull on bones. If bones were strong and tough but not rigid, rapid muscle contractions would cause them to bend alarmingly and would slow the angular movement of limbs.

Tendon, ligament and fascia

Tendons, ligaments and fascia consist primarily of densely packed collagen type I fibres, an arrangement that gives these structures very high tensile strength: the crimped structure of the collagen fibre bundles permits stretching by 10–15% before failure. This combination of strength and extensibility enables tendons, ligaments and fascia to absorb more strain energy per unit weight than any other biological material, and makes them very effective shock absorbers (Alexander, 1988). An important mechanical difference between tendons and ligaments is that ligaments often contain bundles of collagen fibres orientated in a range of directions, presumably because bones can be moved apart in a range of directions, whereas the fibres in a tendon are aligned only in the direction in which the muscle pulls on the tendon. Fascia usually contains collagen fibres aligned to resist forces in at least two different directions.

Hyaline cartilage

Hyaline cartilage consists mainly of very fine collagen type II fibrils and large proteoglycan molecules which have the property of attracting water and swelling. Collagen gives cartilage its tensile strength and stiffness, and the proteoglycans give the tissue a high water content that confers compressive ‘turgor’. During growth and healing, proteoglycans enable the growing cartilage to swell and occupy space that later will be strengthened by other components of the matrix. Articular cartilage is a particular type of hyaline cartilage that covers the ends of articulating bones: the high water content of the tissue enables it to distribute loading evenly on the underlying bone. Because cartilage is softer than bone, it exhibits a relatively greater degree of
deformation when loaded. This increases the area of contact between articular surfaces and reduces the contact stress (Fig. 5.57). Sustained loading of a synovial joint for just a few minutes causes substantial cartilage creep, because water is expelled from the tissue. Creep causes the area of contact to increase, and further reduces the contact stress. Creep in articular cartilage also causes water to be exuded into the joint cavity, assisting in fluid film lubrication (see below). Articular cartilage ‘wear’ (measured in grammes) is the gradual loss of material from the surface in response to high and repetitive loading; it is minimized because the collagen type II fibrils in the superficial zone are aligned parallel to the surface, an arrangement that provides maximal resistance to surface splitting and the subsequent loss of tissue.

![Fig. 5.57](image)

**Fig. 5.57** Articular cartilage in a synovial joint is not as stiff as the underlying bone, so the presence of cartilage in a loaded joint increases the area of contact (B) compared to a joint without cartilage (A).

**Fibrocartilage and elastic cartilage**

Fibrocartilage and elastic cartilage combine the high proteoglycan and water content that characterizes cartilage with a high proportion of either thick collagen type I fibres (fibrocartilage) or elastin fibres (elastic cartilage). Collagen type I confers extra tensile strength and toughness, whereas elastin fibres provides elastic recoil, i.e. the ability to spring back to shape after large deformations.
**MECHANICAL PROPERTIES OF SKELETAL STRUCTURES**

**Long bones**

Long bones are characterized by enlarged ends covered in cartilage, a long hollow shaft, and various bony protuberances. The enlarged ends serve to reduce contact stress where long bones meet in synovial joints, and to increase the stability of such joints (Fig. 5.58). A different relationship between stability and mobility can exist in different anatomic planes, even for the same joint, e.g. the knee joint favours stability in the frontal plane, and mobility in the sagittal plane. The hollow shaft of a long bone confers high strength in bending, but also minimizes bone mass and so increases the speed of movement. Bending strength is increased by having as much bone mass as possible far from the axis of bending (Fig. 5.59). The precise cross-sectional shape of a long bone therefore gives a clear indication of the planes in which the shaft is most likely to be subjected to severe bending. Bony prominences or processes on long bones serve to increase the lever arm of muscles that are attached to them: if a large prominence is close to the centre of rotation of a joint, then the lever arm might increase by over 100%, and the maximum torque developed by the muscle about that centre of rotation would increase by the same amount.
In synovial joints, the shapes of the opposing bone ends largely determine how much movement is possible, and the stability of the joint. Tapered bone ends (A) lead to high mobility, but low stability (in the plane of the page). Conversely, very wide bone ends (C) lead to low mobility and high stability. Some joints resemble (A) in one plane, but (B) or (C) in others.
Synovial joints

Typically, synovial joints are designed for full and free movements, but they must also provide some stability in specific planes (Fig. 5.58). In a joint with a small range of movement, intrinsic stability provided by the articular surfaces and ligaments of that joint may be more important than the extrinsic stability provided by surrounding muscles. Low friction movement is facilitated by the smooth surfaces of articular cartilage, made slippery by the presence of hydrophobic lubricants (surface-active phospholipids) which are bound to the cartilage surface. This boundary lubrication reduces friction during slow movements, especially when forces are high. During rapid movements, microscopic undulations in the cartilage surface trap small quantities of synovial fluid between the articular surfaces, so that fluid film lubrication (akin to aquaplaning) can also occur (Fig. 5.60), and friction and wear are greatly reduced. The sticky, viscous nature of synovial fluid enables it to persist between the cartilage surfaces for longer than water, which would be squeezed out much too quickly. Fluid film lubrication is assisted by joint incongruity, in which the opposing articular surfaces have slightly different curvatures (Fig. 5.61), producing a potential fluid filled gap which moves as the joint moves, washing synovial fluid across the cartilage surfaces. Incongruity can also help to reduce peak loading on the apex of the joint.
The articular cartilage surfaces of synovial joints contain microscopic undulations which trap small quantities of synovial fluid between the surfaces. This enables fluid film lubrication to occur. Boundary lubrication at the points of contact between cartilage asperities is facilitated by lubricants adhering to the cartilage surface.

Some synovial joints are incongruent in the sense that the opposing articular surfaces have slightly different curvatures. This ensures that there is a fluid-filled gap between them when the joint is subjected to low loading (A). Under high loading (B) this gap disappears, but peak loading at the apex of the joint remains lower than it would be if the surfaces had the same curvature, and this is a major advantage for an incongruent joint. The shape of the concave articular surface is sometimes referred to as a Gothic arch. $F =$ Loading force.

**Intervertebral discs**

Intervertebral discs are composed of three tissues: the anulus fibrosus (fibrocartilage), the nucleus pulposus (a hydrated collagenproteoglycan gel), and the endplates (hyaline cartilage) (see Ch. 42). The water content of the nucleus pulposus can reach 90% in children and young adults, enabling the whole tissue to behave like a fluid. When compressive loading is applied to the vertebral column, the fluid pressure in the nucleus presses evenly on the adjacent vertebral bodies, even when they are orientated at small angles to each other. The anulus resists radial expansion of the nucleus, and can deform vertically to facilitate spinal bending in various planes. The relatively dense hyaline cartilage endplate helps to maintain a fluid pressure in the nucleus by slowing down water loss into the vertebral body through perforations in the vertebral endplate. Nevertheless, discs lose approximately 20% of their water gradually, in the course of the day. This nett loss of water is regained at night when, in recumbency, the load on the spine is relieved. Diurnal variations in disc water content cause adults to be approximately 2 cm taller in the early morning, and more flexible in the evening (see Ch. 42).
MUSCLES AND LEVER SYSTEMS

Collagenous architecture of muscle

Muscles are supported by a hierarchy of collagenous sheaths (endomysium, perimysium and epimysium) which surround individual muscle fibres, fascicles and whole muscles respectively. Muscles are bound together into functional groups by collagenous fascia. Together these sheaths create a strong honeycomb structure which contributes to the resistance of a muscle to tension. When muscle is stretched, high tensile forces in these collagenous structures contribute to the high forces which can be generated during eccentric (lengthening) muscle contractions.

Internal muscle forces

Generally speaking, muscle forces exert greater mechanical loading to the skeleton than does body weight. During relaxed standing, 50% of the compressive force acting on the lumbar spine arises from the antagonistic activity of the muscles of the back and abdomen, and 50% comes from superincumbent body weight. However, when bending the trunk to lift weights from the ground, more than 90% of the compressive force acting on the spine can be attributed to muscle tension (Fig. 5.62). Similarly, muscle forces acting on the knee can exceed body weight by a factor of 200–400% during stair climbing, and during deep squatting movements. Muscle forces can exceed the strength of adjacent bones if they contract in alarm, so that normal inhibitory reflexes are suppressed: it is not uncommon for vertebrae to be crushed by muscle tension during major epileptic fits. Muscle forces also rise to high levels when attempting to accelerate body parts. According to Newton’s 2nd Law of motion (force = mass × acceleration), it follows that any attempt to achieve maximum acceleration, e.g. during some sporting activity, will naturally require maximal muscle tension. The size and potential dangers of internal muscle forces are often overlooked, leading some authors to draw spurious distinctions between weight-bearing and non-weight-bearing joints, and suggesting erroneously that only the former are subjected to high loading: it is likely that a watch-maker's finger joints are subjected to stresses as high, and as often, as those applied to his ankles.
During manual labour, muscle tension often rises to high levels in order to generate sufficient bending moment to move external objects. In this example, the back muscles act only a short distance (d) from the pivot point in the intervertebral discs, whereas the weight being lifted acts on a much bigger lever arm (D). In order for the moments to balance, the back muscle tension (F) must exceed the weight being lifted (W) by the ratio of D/d. In practice, this can lead to the lumbar spine being compressed by approximately 500 kg during moderate manual handling.

*Muscle lever systems*

Muscle tension generates bending moments and torques about joints. Moments and torques depend on lever arms as well as muscle forces. It is
conventional (although not particularly instructive) to distinguish between three types of muscle lever system (Fig. 5.63). The length of the lever arm (the perpendicular distance between the muscle line of action and the centre of rotation of the joint) is more important than lever type (Fig. 5.64). If the lever arm is short, then a given muscle contraction will move the joint through a large angle, so the lever system is suited to large and/or rapid movements of that joint. Conversely, a long lever arm leads to small and/or slow movements, but greater moment generation. These considerations can reveal, for example, whether an animal's jaws are designed to catch insects, or to crush nuts. Elite weight-lifters may have muscle insertions with particularly large lever arms about particular joints.
Muscle lever systems can be classified as First class (A), Second class (B) or Third class (C) according to the relative positions of the pivot, the muscle insertion, and the externally-applied force.

The precise location of a muscle insertion relative to a joint greatly influences the function of that joint. A, If the perpendicular distance (d) between the muscle line of action and the centre of rotation of the joint (•) is large, then the joint is suited to slow but forceful movements. B, If d is small, then the joint is suited to rapid but less forceful movements.
MOVEMENTS

Movements of bones

Movement of a bone is referred to as translation if it does not involve any change in orientation relative to a fixed frame of reference (or to another bone). A pure rotation involves no translation, merely a pivoting of the bone about some fixed point or centre of rotation. Spin is the rotation of a bone about its mechanical axis, which for a long bone would coincide with its long axis. Spin can occur in conjunction with other joint rotations (Fig. 5.65). Most body movements involve some combination of rotation, translation, and spin, although the translational component is often small.

\[
(90° + 90° + 90°) \cdot (90° + 90°) = 90°
\]

Fig. 5.65 Complex movements of the body's joints are sometimes required to produce apparently simple movements of the limbs. In this example, moving the hand as shown from A to B to C requires a hidden 'spin' movement of the arm of 90° about its mechanical (long) axis.
Movements at articular surfaces

Opposing joint surfaces are never perfectly congruent. Nevertheless, substantial regions of opposing surfaces may fit together exactly in a certain position known as the close-packed position in which the joint is most stable, e.g. the close-packed position of the knee joint corresponds to full extension. In other (loose-packed) positions, the surfaces of incongruent joints are not perfectly matched, and are able to move relative to each other by a combination of spin, roll and slide (Fig. 5.66). In final close-packing, surfaces are fully congruent, in maximal contact and tightly compressed or ‘screwed-home’. The fibrous capsule and ligaments are maximally spiralized and tensed, and no further movement is possible. Close-packed surfaces cannot be separated by normal external force (as they may be in other positions), and bones can be regarded as temporarily locked, as if no joint existed. Close-packing is a final, limiting position, and any force which tends to further change can only be resisted by contraction of appropriate muscles. Failure to stop further movement results in injury to joint structures. Therefore movement just short of close-packing is physiologically most important.

![Fig. 5.66](image)

The surfaces of incongruent joints move relative to each other by various combinations of spin, roll, and slide.

Ligaments and articular cartilage are to a small degree elastically deformable: in the final stages of close-packing the articular position is an equilibrium between the external moments and torques applied (often by gravity) and resistance to tissue deformation by the tense, twisted capsule and compressed cartilage surfaces. In symmetrical standing, the knee and hip joints approach close-packed positions sufficiently to maintain an erect posture with minimal energy. In all other positions the articular surfaces are not congruent and parts of the capsule are lax; the joint is said to be loose-packed. According to MacConaill & Basmajian (1977) the close- and loose-packed positions of joints are as shown in Table 5.4. Capsules are sufficiently lax near the mid-range of many movements to allow separation of the articulating surfaces by external forces. Opinions may vary in connection with some of the positions in Table 5.4, e.g. a close-packed position may possibly occur in occasional joints at both extremes of the range of movement. It is difficult to assess the situation
in small tarsal and carpal joints and the first carpometacarpal joints. Intervertebral movements are the result of integrated simultaneous changes at all elements which make up the intervertebral articular complex, and perhaps should not be included in Table 5.4. However, most of the positions given do correspond with postures adopted when maximal stress is encountered.

**Centre of rotation**

The centre of rotation is a theoretical concept and may not correspond closely to any anatomical landmark. For a finite movement of one bone relative to a fixed reference (perhaps an anatomical plane), the centre of rotation can be located by (i) drawing theoretical lines between the initial and final positions of anatomical landmarks on the bone, and (ii) determining where the perpendicular bisectors of these lines meet (Fig. 5.67). Real movements of real joints often involve varying combinations of rotation and translation as the movement progresses. It can be instructive to break the whole movement down into a series of small movements, calculate the centre of rotation for each one, and then join up the centres to create the locus of the instantaneous centre of rotation for the whole movement. Joint disease sometimes leads to an abnormally long and tortuous locus of the centre of rotation, because degenerative changes can reduce the restraint to motion offered by one or more tissues.
Fig. 5.67 When a bone is rotated, the centre of rotation (CoR) can be located by (i) drawing lines between the initial and final positions of anatomical landmarks on the bone, and (ii) determining where the perpendicular bisectors of these lines meet. The CoR may not correspond to a precise anatomical landmark.

Coupled movements

An attempt to move a joint in one plane sometimes causes articular surfaces to meet at an oblique angle, which can cause small rotations in other planes. These secondary rotations, which are usually smaller than the primary rotations, are referred to as coupled movements. As an example, lateral bending of the lumbar spine, which occurs in the coronal plane, also normally produces coupled axial rotations. Joint pathology can lead to abnormal coupled movements.
MECHANOBIOLOGY

Adaptive remodelling

Skeletal tissues are generally able to adapt their mechanical properties to match the forces applied to them. This process is best understood for bone, and bone biologists refer to this general principle as Wolff’s Law. As illustrated in Fig. 5.68, the degree of deformation of a tissue is proportional to the amount of mechanical loading to which it is subjected. Cells detect this increased strain and respond by producing more extracellular matrix, which increases the modulus (stiffness) of the tissue and returns strain levels to normal. Similarly, reduced loading leads to reduced tissue strain, reduced matrix synthesis, and reduced modulus, so that tissue strain increases to normal values. This negative feedback system ensures that bone adapts (remodels) to suit its mechanical environment. Animal experiments suggest that as few as 36 relatively severe loading cycles per day are sufficient to produce a maximal hypertrophic response in bone, whereas fewer than four loading cycles per day leads to tissue resorption. Evidently, bone cells respond to maximal loading rather than time-averaged loading. There is some experimental evidence that cartilage and tendon likewise adapt to their mechanical environment. It would be unlikely that they did not, because the mechanical properties of adjacent tissues would rapidly become mis-matched, increasing the risk of damage to one of them. However, it is equally evident that different tissues cannot adapt at the same rates. Highly vascularized tissues such as muscle and bone have the potential to adapt rapidly, whereas poorly vascularized tissues such as large tendons do not. Avascular tissues such as articular cartilage and intervertebral discs can adapt only very slowly, so that turnover times for some matrix macromolecules can be as long as 100 years. Large differences in adaptive potential between adjacent musculoskeletal tissues could lead to problems in the less well-vascularized tissue when levels of mechanical loading increase abruptly.

![Fig. 5.68](image_url) Adaptive remodelling is the process by which musculoskeletal tissues adapt to prevailing mechanical demands. If a tissue is subjected to increased mechanical loading (right) it deforms more. Cells respond to this increased strain by depositing more matrix and increasing its modulus (stiffness) until strain levels return to normal. Similarly, reduced loading leads to reduced tissue strain (left), reduced modulus, and reduced matrix deposition until strain levels rise to normal.

Mechanotransduction

Various mechanisms have been proposed to explain how cells in musculoskeletal tissues detect mechanical loading. Cells in bone appear to respond to tissue strain, possibly by detecting fluid flow within the microscopic canaliculi of the matrix.
Cells in cartilage and ligaments also appear able to detect tissue strain, possibly because fluid flow in the surrounding matrix deforms the cells in shear (Fig. 5.52). Cells in articular cartilage and in the nucleus pulposus of intervertebral discs can detect hydrostatic pressure in the surrounding medium, although only the cells in the nucleus would normally experience such a pressure in life. Muscle cells respond to strain and microinjury. Mechanotransduction appears to be mediated by matrix molecules such as fibronectin, by transmembrane proteins such as integrins, and by a range of intracellular proteins such as titin in muscle.

**Degeneration, injury and frustrated repair**

Numerous theories have been propounded to explain degenerative changes in skeletal tissues. Most presume that the cells behave abnormally, possibly because of an unfavourable genetic inheritance, so that the matrix becomes weakened and physically disrupted. Alternatively, degenerative changes may represent an attempt by the cells to repair a matrix where the primary cause of damage has been excessive mechanical loading. In poorly vascularized tissues, such as cartilage and tendon, low cell density and inadequate transportation of metabolites could lead to a vicious circle of minor injury, frustrated repair, tissue weakening, and further injury.

CHAPTER 6 – Smooth muscle and the cardiovascular and lymphatic systems

The cardiovascular system carries blood from the heart to all parts of the body through a series of tubes, all but the smallest of which are muscular. The muscle in these tubes is of two types: smooth muscle is characteristic of the walls of blood vessels and cardiac muscle provides the walls of the heart chambers with their powerful contractile pumping action. The general characteristics and classification of muscle tissues are given on page 103. Smooth muscle also forms an important contractile element in the walls of many other organ systems of the body, e.g. the gastrointestinal tract.

SMOOTH MUSCLE

In smooth muscle tissue the contractile proteins actin and myosin are not organized into regular sarcomeres, visible as transverse striations, so the cytoplasm has a smooth (unstriated) appearance. Smooth muscle is also referred to as involuntary muscle, because its activity is neither initiated nor monitored consciously. It is more variable, in both form and function, than either striated or cardiac muscle, a reflection of its varied roles in different systems of the body.

Smooth muscle cells (fibres) are smaller than those of striated muscle. Their length can range from 15 µm in small blood vessels to 200 µm, and even to 500 µm or more in the uterus during pregnancy. The cells are spindle-shaped, tapering towards the ends from a central diameter of 3–8 µm (Fig. 6.1). The nucleus is single, located at the midpoint, and often twisted into a corkscrew shape by the contraction of the cell. Smooth muscle cells aggregate with their long axes parallel and staggered longitudinally, so that the wide central portion of one cell lies next to the tapered end of another. Such an arrangement achieves both close packing and a more efficient transfer of force from cell to cell. In transverse section, smooth muscle is seen as an array of circular or slightly polygonal profiles of very varied size, and nuclei are present only in the centres of the largest profiles (Fig. 6.2). This appearance contrasts markedly with that of skeletal muscle cells, which show a consistent diameter in cross-section and peripherally placed nuclei throughout their length.
Fig. 6.1 Smooth muscle cells (fibres) in transverse (above) and longitudinal (below) section in the human intestinal wall. Individual cells are spindle-shaped with a single central nucleus, aligned in parallel with neighbouring cells in a fasciculus.
Smooth muscle is typically found in the walls of tubular structures and hollow viscera. It regulates diameter (e.g. in blood vessels, and branches of the bronchial tree); propels liquids or solids (e.g. in the ureter, hepatic duct, and intestines); or expels the contents (e.g. in the urinary bladder and uterus). The actual arrangement of the cells varies with the tissue. The account that follows will therefore be concerned with the generic properties of smooth muscle. The more specialized morphologies of smooth muscle are described in the appropriate regional chapters.

Smooth muscle has no attachment structures equivalent to the fasciae, tendons and aponeuroses associated with skeletal muscle. There is a special arrangement for transmitting force from cell to cell and, where necessary, to other soft tissue structures. Cells are separated by a gap of 40–80 nm. Each cell is covered almost
entirely by a prominent basal lamina which merges with a reticular layer consisting of a network of fine elastin, reticular fibres (collagen type III) and type I collagen fibres (Fig. 6.3). These elements bridge the gaps between adjacent cells and provide mechanical continuity throughout the fascicle. The cell attaches to components of this extracellular matrix at dense plaques (see Fig. 6.4A) where the basal lamina is thickened; cell–cell attachment occurs at intermediate junctions or desmosomes, formed of two adjacent dense plaques. At the boundaries of fascicles, the connective tissue fibres become interwoven with those of interfascicular septa, so that the contraction of different fascicles is communicated throughout the tissue and to neighbouring structures. The components of the reticular network, the ground substance and collagen and elastic fibres, are synthesized by the smooth muscle cells themselves, not by fibroblasts or other connective tissue cells, which are rarely found within fasciculi.

Fig. 6.3  A. Three-dimensional representation of smooth muscle cells. For clarity, some structural features have been separated for illustration in different cells. The spindle-shaped cells interdigitate with their long axes parallel; mechanical continuity between the cells is provided by a reticular layer of elastin and collagen fibres. The cytoskeletal framework
consists of intermediate filament arrays (mainly longitudinal) and bundles of actin and myosin filaments (shown in separate cells) inserted into cytoplasmic dense bodies and submembraneous dense plaques to form a three-dimensional network. The sarcolemma contains anchoring desmosomes (adherens junctions), gap junctions and caveolae. B. The concertina-like change in shape of smooth muscle cells as they contract.

Fig. 6.4 Electron micrographs showing the characteristic features of smooth muscle cells. Vascular smooth muscle in human kidney tissue, showing a cytoplasm packed densely with microfilaments (actin and myosin), cytoplasmic dense bodies (arrows) and submembraneous dense plaques (arrowheads). A basal lamina encloses the cell. Inset shows four caveolae (C) (vesicular invaginations of the cell surface at high magnification. These are associated with receptors, enzymes and ion channels important in smooth muscle function.

In some blood vessels, notably those of the pulmonary circulation, and in the airways, and probably in other smooth muscle types, there is evidence for heterogeneity of cell phenotype. Some myofibroblast-like cells have a function that is more secretory than contractile. The secretory phenotype is often increased in disease (e.g. chronic severe asthma, pulmonary hypertension) and is associated with increased proliferation and remodeling, also the secretion of cytokines and other mediators. Many smooth muscles seem to exhibit considerable plasticity between these contractile and secretory phenotypes.

Discontinuities occur in the basal lamina between adjacent cells, and here the cell membranes approach to 2–4 nm of one another to form a gap junction (Fig. 6.2). These junctions are believed to be structurally similar to their counterparts in cardiac muscle. They provide a low-resistance pathway through which electrical excitation can pass between cells, producing a coordinated wave of contraction. The incidence of gap junctions varies with the anatomical site of the tissue: they appear to be more
abundant in the type of smooth muscle which generates rhythmic (phasic) activity. Although some smooth muscles can generate as much force per unit cross-sectional area as skeletal muscle, the force always develops much more slowly than in striated muscle. Smooth muscle can contract by more than 80%, a much greater range of shortening than the 30% or so to which striated muscle is limited. The significance of this property is illustrated by the urinary bladder, which is capable of emptying completely from an internal volume of 300 ml or more. Smooth muscles can maintain tension for long periods with very little expenditure of energy. Many smooth muscle structures are able to generate spontaneous contractions: examples are found in the walls of the intestines, ureter and uterine tube.

**MICROSTRUCTURE OF SMOOTH MUSCLE AND THE CONTRACTILE MECHANISM**

Although electron microscopy revealed the presence of filaments in smooth muscle some years ago, this observation alone provided little insight into their mode of function because of the lack of any obvious organization of the filaments. More recent work, using high-resolution immunocytochemistry, has revealed further details of the internal architecture of the cell and suggests a structural basis for contractile function. The model, which is illustrated in Fig. 6.3, depends on the mutual interaction of two systems of filaments, one forming the cytoskeleton and the other the contractile apparatus.

Excluding the perinuclear region, the cytoplasm of a smooth muscle cell effectively consists of two structural domains. The cytoskeleton forms a structural framework that maintains the spindle-like form of the cell and provides an internal scaffold with which other elements can interact. Its major structural component is the intermediate filament desmin, with the addition of vimentin (which may also be present alone) in vascular smooth muscle. The intermediate filaments are arranged mainly in longitudinal bundles, but some filaments interconnect the bundles with each other and with the sarcolemma to form a three-dimensional network. The bundles of intermediate filaments insert into focal, electron-dense bodies, approximately 0.1 µm in diameter, which are distributed uniformly throughout the cytoplasm and also attach to dense plaques underlying the plasma membrane (Fig. 6.3A). The cytoplasmic dense bodies and submembraneous dense plaques are equivalent to the Z-discs of striated muscle cells. They contain the actin-binding protein α-actinin and thus also anchor the actin filaments of the contractile apparatus. These form a lattice of obliquely arranged bundles throughout the cytoplasm, which transmit force to the plasma membrane and thus the basal lamina and extracellular matrix via dense plaques. These are associated with a highly structured arrangement of ancillary proteins, including vinculin and talin, which in turn attach to integrins that cross the membrane and provide attachment to components of the extracellular matrix. An analogous arrangement underlies cell–cell attachment at desmosomes, but here the attachment between dense plaques is provided by transmembrane cadherin glycoproteins and intracellular catenins instead of integrins and talin. Mechanical deformation of the cell may be linked to cell signalling mechanisms via focal adhesion kinase (FAK) and its substrate paxillin; phosphorylation of talin and paxillin may modulate the deformability of the smooth muscle cell. Other regulatory proteins also associate specifically with actin, such as caldesmon and calponin. The cytoskeleton is therefore not a passive structure, and can adapt dynamically to load, presumably.
therefore contributing to the low energy requirements of smooth muscle contraction. The ratio of actin to myosin is about eight times greater in smooth compared to striated muscle, reflecting the greater length of actin filaments in smooth muscle.

Smooth muscle myosin filaments are 1.5–2 µm long, somewhat longer than those of striated muscle. Although smooth muscle cells contain less myosin, the longer filaments are capable of generating considerable force. The myosin filaments of smooth muscle are also assembled differently, such that their head regions lie symmetrically on either side of a ribbon-like filament, rather than imposing a bipolar organization on the filament. Actin filaments, to which they bind, can thus slide along the whole length of the myosin filament during contraction. This difference underpins the ability of smooth muscle to undergo much greater changes in length than striated muscle. Actin–myosin filament sliding generates tension which transmits to focal regions of the plasma membrane, changing the cell to a shorter, more rounded shape (Fig. 6.3B) and often deforming the nucleus to a corkscrew-like profile.

Caveolae, cup-like invaginations of the plasma membrane with a resemblance to endocytotic vesicles, are a characteristic feature of smooth muscle cells, and may form up to 30% of the membrane (Fig. 6.4). They are associated with many receptors, ion channels and kinases, and the peripheral sarcoplasmic reticulum and may thus act as sites for highly localized signalling pathways. They may also act as specialized pinocytotic structures involved in fluid and electrolyte transport into the cell. Other organelles (mitochondria, ribosomes etc) are largely confined to the filament-free perinuclear cytoplasm, although in some smooth muscle types, including vascular smooth muscle, peripheral mitochondria, sarcoplasmic reticulum and sarcolemma seem to form signalling microdomains. Recent studies using mitochondria-specific staining of such smooth muscle cells often show mitochondria forming a reticular network within the cytosol, which would be consistent with a cell signalling function, especially that concerned with intracellular calcium homeostasis.
VASCULAR SUPPLY

The blood supply of smooth muscle is less extensive than that of striated muscle. Where the tissue is not too densely packed, afferent and efferent vessels gain access via connective tissue septa, and capillaries run in the connective tissue between small fascicles. However, unlike striated muscle, capillaries are not found in relation to individual cells.
Smooth muscle may contract in response to nervous or hormonal stimulation, or electrical depolarization transferred from neighbouring cells. Some muscles receive a dense innervation to all cells; these are often referred to as multi-unit smooth muscles, and most blood vessels are of this type. Such innervation can precisely define contractile activity, e.g. in the iris, specific nervous control can produce either pupillary constriction or dilation. Other muscles are more sparsely innervated. They tend to display myogenic activity, initiated spontaneously or in response to stretch, which may be markedly influenced by hormones. In these muscles, which include those in the walls of the gastrointestinal tract, urinary bladder, ureter, uterus and uterine tube, innervation tends to exert a more global influence on the rate and force of intrinsically generated contractions. These muscles have been referred to as unitary smooth muscles. The terms multi-unit and unitary smooth muscles are widely used, but in practice such distinctions are better regarded as the extremes of a continuous spectrum.

Smooth muscles are innervated by unmyelinated axons whose cell bodies are located in autonomic ganglia, either in the sympathetic chain or, in the case of parasympathetic fibres, closer to the point of innervation (Fig. 6.5). They ramify extensively, spreading over a large area of the muscle and sending branches into the muscle fasciculi. The terminal portion of each axonal branch is beaded, and consists of expanded portions, varicosities, packed with vesicles and mitochondria, separated by thin, intervaricose portions. Each varicosity is regarded as a transmitter release site, and, in the functional sense, is therefore a nerve ending. In this way the axonal arborization of a single autonomic neurone bears a very large number of nerve endings (up to tens of thousands), as opposed to a maximum of a few hundred in somatic motor neurones. The neuromuscular terminals of autonomic efferents are considered in more detail on page 62.
The neuromuscular junctions in smooth muscles do not show the consistent appearance seen in skeletal muscles. The neurotransmitter diffuses across a gap that can vary from 10 to 100 nm: even separations up to 1 µm may still allow neuromuscular transmission to take place, although more slowly. The nerve ending is packed with vesicles, but the adjacent area of the muscle cell is not structurally differentiated from that of non-junctional regions – there is no distinct synapse.

Intramuscular afferent nerves are the peripheral processes of small sensory neurones in the dorsal root ganglia. Since they are unmyelinated, contain axonal vesicles and have a beaded appearance, they are difficult to distinguish from efferent fibres, except by differential staining for neurotransmitters.
EXCITATION–CONTRACTION COUPLING IN SMOOTH MUSCLE

Excitation–contraction coupling in smooth muscle may be electromechanical or pharmacomechanical. Electromechanical coupling involves depolarization of the cell membrane by an action potential, and may be generated when a membrane receptor, usually linked with an ion channel, is occupied by a neurotransmitter, hormone or other blood-borne substance. It is most commonly seen in unitary smooth muscles such as those of the viscera, with transmission of electrical excitation from cell to cell via gap junctions. In some types of smooth muscle, depolarization may be the consequence of other stimuli, such as cooling, stretching, and even light.

Pharmacomechanical coupling is a receptor-mediated and G-protein coupled process, which can activate constriction via several pathways. These include triggering the formation of inositol trisphosphate, which acts as a signal for intracellular calcium release from the sarcoplasmic reticulum, activation of voltage-independent calcium channels in the sarcolemma, and depolarization causing activation of voltage-dependent calcium channels. In addition, some receptors couple to kinases that modulate contraction in a calcium independent fashion, either via myosin phosphatase (see below), or via the actin cytoskeleton. Different types of smooth muscle use these pathways to differing extents.

The regulation of contraction of smooth muscle is however largely calcium-dependent. In the cytoplasm, calcium binds to calmodulin. The complex so formed regulates the activity of myosin light chain kinase, which phosphorylates myosin regulatory light chains and initiates the myosin-actin ATPase cycle (p. 111). The enzymatic activation process is therefore inherently slow. Unphosphorylated myosin II of smooth muscle cannot initiate actin binding, although it can maintain contraction, with little energy expenditure. Myosin phosphatase dephosphorylates myosin light chains, and thus promotes relaxation. Inhibition of the phosphatase, for example by Rho kinase, increases phosphorylation for any level of calcium (i.e. increases calcium sensitivity). This is now believed to be a very important component of the response to many constrictor agonists.
DEVELOPMENT

It was thought that all smooth muscle cells developed \textit{in situ} exclusively from the splanchnopleuric mesenchyme in the walls of the anlagen of the viscera and around the endothelium of blood vessels. However, recent experimental studies have traced the progeny of cells proliferating from the epithelial plate of the somite and have identified endothelial and tunica media smooth muscle cells arising from individual somites (Scaal & Christ 2004). The origin of the smooth muscle of the iris is still unclear. This region of the eye develops from the optic cup, and so the smooth muscle which arises there is derived either from the neurectoderm of the original optic cup or from the neural crest mesenchyme which later invades the iris.

Following a period of proliferation, clusters of myoblasts become elongated in the same orientation. Dense bodies, associated with actin and cytoskeletal filaments, appear in the cytoplasm, and the surface membrane starts to acquire its specialized features, i.e. caveolae, adherens junctions and gap junctions. Cytoskeletal filaments extend to insert into the submembranous dense plaques and cytoplasmic dense bodies. Thick filaments are seen a few days after the first appearance of thin filaments and intermediate filaments, and from this time the cells are able to contract. During development, dense bodies increase in number and further elements of the cytoskeleton are added. In addition to synthesizing the cytoskeleton and contractile apparatus, the differentiating cells express and secrete components of the extracellular matrix.

In a developing smooth muscle all the cells express characteristics of the same stage of differentiation, and there are no successive waves of differentiation. From its earliest appearance to maturity, a smooth muscle increases several hundredfold in mass, partly by a 2- to 4-fold increase in the size of individual cells, but mainly by a very large increase in cell number. Growth occurs by division of cells in every part of the muscle, not just at its surface or ends. Mitosis occurs in cells in which differentiation is already well advanced, as evidenced by the presence of myofilaments and membrane specializations. Mitotic smooth muscle cells may be found at any stage of life, but their numbers peak before birth, at a time that differs for different muscles; they are rare in the adult unless the tissue is stimulated to hypertrophy (as in the pregnant uterus) or to repair. The ability of mature cells to undergo mitosis therefore differs between the three major types of muscle: skeletal muscle cells cannot divide at all after differentiation; cardiac muscle cells can divide, but only before birth; and smooth muscle cells appear to remain capable of division throughout life.

During the early stages of development, smooth muscle expresses embryonic and non-muscle isoforms of myosin. The proportions of these isoforms decrease progressively. Initially, SM-1 is the dominant or exclusive
smooth muscle heavy chain isoform: the SM-2 isoform becomes more established later. For a review of the development of vascular smooth muscle see Owens, Kumar and Wamhoff (2004).
THE CARDIOVASCULAR AND LYMPHATIC SYSTEMS

GENERAL ORGANIZATION

Cells of peripheral blood, suspended in plasma, circulate through the body in the blood vascular system. Interstitial fluid from peripheral tissues returns to the blood vascular system via the lymphatic system, which also provides a channel for the migration of leukocytes and the absorption of certain nutrients from the gut.

The cardiovascular system carries nutrients, oxygen, hormones, etc. throughout the body and the blood redistributes and disperses heat. As a consequence of the hydrostatic pressure, the system also has mechanical effects, such as maintaining tissue turgidity and counteracting the effects of gravity. Blood circulates within a fast, high capacity system made up of the heart, which is the central pump and main motor of the system; arteries, which lead away from the heart and carry the blood to the peripheral parts of the body; and veins, which return the blood to the heart. The heart can be thought of as a pair of muscular pumps, one feeding a minor loop (pulmonary circulation), which serves the lungs and oxygenates the blood, the other feeding a major loop (systemic circulation), which serves the rest of the body. With limited exceptions, each loop is a closed system of tubes, so that blood per se does not usually leave the circulation.

From the centre to the periphery, the vascular tree shows three main modifications. The arteries increase in number by repeated bifurcation and by sending out side branches, in both the systemic and the pulmonary circulation. For example, the aorta, which carries blood from the heart to the systemic circulation, gives rise to about $4 \times 10^6$ arterioles and four times as many capillaries. The arteries also decrease in diameter, although not to the same extent as their increase in number, so that a hypothetical cross-section of all the vessels at a given distance will increase in total area with increasing distance from the heart. At its emergence from the heart, the aorta of an adult man has an outer diameter of approximately 30 mm (cross-sectional area of nearly $7 \text{ cm}^2$). The diameter decreases along the arterial tree until it is as little as 10 $\mu$m in arterioles (each with a cross-sectional area of about $80 \mu\text{m}^2$). However, given the enormous number of arterioles, the total cross-sectional area at this level is approximately 150 $\text{cm}^2$, more than 200 times that of the aorta. As a result, blood flow is faster near the heart than at the periphery.

The walls of arteries decrease in thickness towards the periphery, although this is not as substantial as the reduction in vessel diameter. Consequently, in the smallest arteries (arterioles), the thickness of the wall represents about half the outer radius of the vessel, whereas in a large vessel it represents between one-fifteenth and one-fifth, e.g. in the thoracic aorta the radius is approximately 17 mm and the wall thickness 1.1 mm.

Venules, which return blood from the periphery, converge on each other forming a progressively smaller number of veins of increasingly large size. As with arteries, the hypothetical total cross-sectional area of all veins at a given level reduces nearer to the heart. Eventually, only the two largest veins, the superior and inferior venae cavae, open into the heart from the systemic circulation. A similar pattern is found in the pulmonary circulation, but here the vascular loop is shorter and has fewer branch
points, and consequently, the number of vessels is smaller than in the systemic circulation. The total end-to-end length of the vascular network in a typical adult is twice the circumference of the earth.

Large arteries, such as the thoracic aorta, subclavian, axillary, femoral and popliteal arteries, lie close to a single vein which drains the same territory as that supplied by the artery. Other arteries are usually flanked by two veins, satellite veins (venae comitantes), which lie on either side of the artery, and have numerous cross-connections: the whole is enclosed in a single connective tissue sheath. The artery and the two satellite veins are often associated with a nerve, and when they are surrounded by a common connective tissue sheath they form a neurovascular bundle.

The close association between the larger arteries and veins in the limbs allows the counterflow exchange of heat to take place. This mechanism promotes heat transfer from arterial to venous blood, and thus helps to preserve body heat. Counterflow heat exchange systems are found in certain organs, e.g. in the testis, where the pampiniform plexus of veins surrounds the testicular artery (this arrangement not only conserves body heat, but also maintains the temperature of the testis below average body temperature). Counterflow ion exchange mechanisms are found in the microcirculation, as in the arterial and venous sinusoids of the vasa recta in the renal medulla. Here, countercurrent exchange retains sodium ions at a high concentration in the medullary interstitium, and efferent venous blood transfers sodium ions to the afferent arterial supply.

Arteries and veins are named primarily according to their anatomical position. In functional terms, three main classes of vessel are described: resistance vessels (arteries, but mainly arterioles), exchange vessels (capillaries, sinusoids and small venules) and capacitance vessels (veins). Structurally, arteries can also be divided into elastic and muscular types. Although muscle cells and elastic tissue are present in all arteries, the relative amount of elastic material is greatest in the largest vessels, whereas the relative amount of smooth muscle increases progressively towards the smallest arteries.

Arteries may also be subdivided into conducting and distributing, as well as resistance, vessels. The large conducting arteries which arise from the heart, together with their main branches, are characterized by the predominantly elastic properties of their walls. Distributing vessels are smaller arteries supplying the individual organs, and their wall is characterized by a well-developed muscular component. Resistance vessels are mainly arterioles. Small and muscular, they provide the main source of the peripheral resistance to blood flow, and they cause a marked drop in the pressure of blood which flows into the capillary beds within tissues.

Capillaries, sinusoids and small (postcapillary) venules are collectively termed exchange vessels. Their walls allow exchange between blood and the interstitial tissue fluid which surrounds all cells: this is the essential function of a circulatory system. Arterioles, capillaries and venules constitute the microvascular bed, the structural basis of the microcirculation.

Larger venules and veins form an extensive, but variable, large-volume, low-pressure system of vessels conveying blood back to the heart. The high capacitance of these vessels is due to the distensibility (compliance) of their walls, so that the content of
blood is high even at low pressures. This part of the vascular bed contains the greatest proportion of blood, reflecting the large relative volume of veins.

Blood from the abdominal part of the digestive tube (with the exception of the lower part of the anal canal), and from the spleen, pancreas and gallbladder, drains to the liver via the portal vein. The portal vein ramifies within the substance of the liver like an artery and ends in the hepatic sinusoids. These drain into the hepatic veins which in turn drain into the inferior vena cava. Blood supplying the abdominal organs thus passes through two sets of capillaries before it returns to the heart. The first provides the organs with oxygenated blood, and the second carries deoxygenated blood, rich in absorption products from the intestine, through the liver parenchyma. A venous portal circulation also connects the median eminence and infundibulum of the hypothalamus with the adenohypophysis. In essence, a venous portal system is a capillary network that lies between two veins, instead of between an artery and a vein, which is the more usual arrangement in the circulation. A capillary network may also be interposed between two arteries, e.g. in the renal glomeruli, where the glomerular capillary bed lies between afferent and efferent arterioles. This maintains a relatively high pressure system, which is important for renal filtration.

A parallel circulatory system in the body is provided by the lymphatic vessels and lymph nodes. Lymphatic vessels originate in peripheral tissues as blind-ended endothelial tubes which collect excess fluid from the interstitial spaces between cells and conduct it as lymph. Lymph is returned to the blood vascular system via lymphatic vessels which converge on the large veins in the root of the neck.

The development of blood vessels is described on pages, 206–208.

General features of vessel walls

Blood vessels, irrespective of size, and with the exception of capillaries and venules, have walls consisting of three concentric layers (tunicae) (see Fig. 6.7). The intima (tunica intima), is the innermost layer. Its main component, the endothelium, lines the entire vascular tree, including the heart, and the lymphatic vessels. The media (tunica media) is made of muscle tissue, elastic fibres and collagen. While it is by far the thickest layer in arteries, the media is absent in capillaries and is comparatively thin in veins. The adventitia (tunica adventitia) is the outer coat of the vessel, and consists of connective tissue, nerves and vessel capillaries (vasa vasorum). It links the vessels to the surrounding tissues. Vessels differ in the relative thicknesses and detailed compositions of their layers and, in the smallest vessels, the number of layers represented.
Large elastic arteries

The aorta and its largest branches (brachiocephalic, common carotid, subclavian and common iliac arteries) are large elastic arteries which conduct blood to the medium-sized distributing arteries.

The intima is made of an endothelium, resting on a basal lamina, and a subendothelial connective tissue layer. The endothelial cells are flat, elongated and polygonal in outline, with their long axes parallel to the direction of blood flow (see Fig. 6.17). The subendothelial layer is well developed, contains elastic fibres and type I collagen fibrils, fibroblasts and small, smooth muscle-like myointimal cells. The latter accumulate lipid with age and in an extreme form, this feature contributes to atherosclerotic changes in the intima. Thickening of the intima progresses with age and is more marked in the distal than in the proximal segment of the aorta.
A prominent internal elastic lamina, sometimes split, lies between intima and media. This lamina is smooth, measures about 1 µm in thickness, and, with the elastic lamellae of the media, is stretched under the effect of systolic pressure, recoiling elastically in diastole. Elastic arteries thus have the effect of sustaining blood flow despite the pulsatile cardiac output. They also smooth out the cyclical pressure wave. The media has a markedly layered structure, in which fenestrated layers of elastin (elastic lamellae) alternate with interlamellar smooth muscle cells (Fig. 6.6), collagen and fine elastic fibres. The arrangement is very regular, such that each elastic lamella and adjacent interlamellar zone is regarded as a ‘lamellar unit’ of the media. In the human aorta there are approximately 52 lamellar units, measuring about 11 µm in thickness. Number and thickness of lamellar units increases during postnatal development, from 40 at birth.
The adventitia is well developed. In addition to collagen and elastic fibres, it contains flattened fibroblasts with extremely long, thin processes, macrophages and mast cells, nerve bundles and lymphatic vessels. The vasa vasorum are usually confined to the adventitia.

**Muscular Arteries**

Muscular arteries are characterized by the predominance of smooth muscle in the media (Fig. 6.8). The intima consists of an endothelium, similar to that of elastic arteries, which rests on a basal lamina and subendothelial connective tissue. The internal elastic lamina (Fig. 6.7, Fig. 6.8) is a distinct, thin layer, sometimes duplicated and occasionally absent. It is thrown into wavy folds as a result of contraction of smooth muscle in the media. Some 75% of the mass of the media consists of smooth muscle cells which run spirally or circumferentially around the vessel wall. The relative amount of extracellular matrix is therefore less than in large arteries; however, fine elastic fibres which run mainly parallel to the muscle cells are present. An external elastic lamina, composed of sheets of elastic fibres, forms a less compact layer than the internal lamina, and separates the media from the adventitia in the larger muscular arteries. The adventitia is made of fibroelastic connective tissue, and can be as thick as the media in the smaller arteries. The inner part of the adventitia contains more elastic than collagen fibres.
Arterioles

In arterioles (Fig. 6.9, Fig. 6.10) the endothelial cells are smaller than in large arteries, but their nuclear region is thicker and often projects markedly into the lumen. The nuclei are elongated and orientated parallel to the vessel length, as is the long axis of the cell. The basal surface of the endothelium contacts a basal lamina, but an internal elastic lamina is either absent or is highly fenestrated and traversed by the cytoplasmic processes of muscle cells or endothelial cells.
Fig. 6.9 A small arteriole (A) and accompanying venule (V) in loose connective tissue (human). Note the relative thicknesses of the vessel walls, in comparison with the diameters of their lumens.
The muscle cells are larger in cytoplasmic volume than those of large arteries and they form a layer one or two cells thick. They are arranged circumferentially and are tightly wound around the endothelium. In the smallest arterioles each cell makes several turns, producing extensive apposition between parts of the same cell. Their contractility controls the flow of blood into the capillary bed, and they act functionally as precapillary sphincters. Constriction of the vessel lumen is thought to be under myogenic, rather than neurogenic, control and is responsive to local vasoactive and metabolic factors. Arteriolar adventitia is very thin.

Arterioles are usually densely innervated by sympathetic fibres, via small bundles of varicose axons packed with transmitter vesicles, mostly of the adrenergic type. The distance between axolemma and muscle cell membrane can be as little as 50–100 nm and the gap is occupied only by a basal lamina. Autonomic neuromuscular junctions are very common in arterioles.

**Capillaries**

The capillary wall (Fig. 6.11) is formed by an endothelium and its basal lamina, plus a few isolated pericytes. Capillaries are the vessels closest to the tissue they supply and their wall is a minimal barrier between blood and the surrounding tissues. Capillary structure varies in different locations. Capillaries measure 4–8 µm in diameter (much more in the case of sinusoids) and are hundreds of microns long. Their lumen is just large enough to admit the passage of single blood cells, usually with considerable deformation. However, the true bottleneck of the circulatory system occurs at the level of the arterioles, where muscle contraction can obliterate the lumen.
Typically a single endothelial cell forms the wall of a capillary, so that the junctional complex occurs between extensions of the same cell. The endothelial cells of some capillaries have fenestrations, or pores, through their cytoplasm. Fenestrations are approximately circular, 50–100 nm in diameter, and at their edge the luminal and abluminal membranes of the endothelial cell come into contact with each other. The fenestration itself is usually occupied by a thin electron-dense diaphragm of unknown molecular composition. Fenestrated capillaries occur in renal glomeruli, where they lack a diaphragm, in intestinal mucosae, and in endocrine and exocrine glands. Fenestrations are almost invariably present in capillaries which lie close to an epithelium, including the skin.
Capillaries without fenestrations, such as those in the brain, striated and smooth muscles, lung and connective tissues, are known as continuous capillaries. Capillary permeability varies greatly among tissues, and this can be correlated partly with the type of endothelium. Where efficient barriers to diffusion of large molecules occur, e.g. brain, thymic cortex and testis, continuous capillary endothelial cells are joined by tight junctions.

**Sinusoids**

Sinusoids are expanded capillaries (Fig. 6.12), and are large and irregular in shape. They have true discontinuities in their walls, allowing intimate contact between blood and the parenchyma. The discontinuities are formed by gaps between endothelial cells, which are also fenestrated, such that the sinusoidal lining, and sometimes also the basal lamina, is incomplete. Sinusoids occur in large numbers in the liver (where a basal lamina is completely absent), spleen, bone marrow, adenohypophysis (Fig. 6.12) and suprarenal medulla.

![Expanded sinusoids (S) typical of endocrine glands and certain other tissues, are seen here containing erythrocytes (orange) in the adenohypophysis. Endocrine cells stain blue, reddish-brown or are poorly stained in this trichrome preparation.](image)

**Venules**

When two or more capillaries converge, the resulting vessel is larger (10–30 µm) and is known as a venule (postcapillary venule). Venules (Fig. 6.9) are essentially tubes of flat, oval or polygonal endothelial cells surrounded by basal lamina and, in the larger vessels, by a delicate adventitia of a few fibroblasts and collagen fibres mainly running longitudinally. Pericytes (see Fig. 6.21) support the walls of these venules.
Postcapillary venules are sites of leukocyte migration. In venules of mucosa-associated lymphoid tissue (MALT), particularly of the gut and bronchi, and in the lymph nodes and thymus, endothelial cells are taller and have intercellular junctions through which lymphocytes and other blood components can readily pass. These are known as high endothelial venules (HEV) (see Figs 6.18, 6.19). Elsewhere, venules are believed to be a major site where migration of neutrophils, macrophages and other leukocytes into extravascular spaces occurs, and where neutrophils may temporarily attach, forming marginated pools.
Fig. 6.18. A high endothelial venule in a human lymph node, sectioned longitudinally, lined by cuboidal endothelium (arrow). Erythrocytes and leukocytes (mainly lymphocytes and neutrophils) are seen in the lumen.
In general, the endothelium of venules has few tight junctions, and is relatively permeable. The intercellular junctions of venules are sensitive to inflammatory agents which increase their permeability to fluids and defensive cells, and facilitate leukocyte extravasation by diapedesis.

Venules do not acquire musculature until they are about 50 µm in outer diameter, when they are known as muscular venules. This distinction is important, because postcapillary venules, which lack muscle in their walls, are as permeable to solutes as capillaries and are thus part of the microcirculatory bed. At the level of the postcapillary venule the cross-sectional area of the vascular tree is at its maximum, and there is a dramatic fall in pressure (from 25 mmHg in the capillary to approximately 5 mmHg). Muscular venules converge to produce a series of veins of progressively larger diameter. Venules and veins are capacitance vessels, i.e. they have thin distensible walls which can hold a large volume of blood and accommodate luminal pressure changes.

Veins

Veins are characterized by a relatively thin wall in comparison to arteries of similar size and by a large capacitance. Wall thickness is not correlated exactly to the size of the vein, and varies in different regions, e.g. the wall is thicker in veins of the leg than it is in veins of a similar size in the arm.

The structural plan of the wall is similar to that of other vessels, except that the amount of muscle is considerably less than in arteries, while collagen and, in some veins, elastic fibres, predominate. In most veins, e.g. those of the limbs, the muscle is arranged approximately circularly. Longitudinal muscle is present in the iliac, brachiocephalic, portal and renal veins and in the superior and inferior venae cavae. Muscular tissue is absent in the maternal placental veins, dural venous sinuses and pial and retinal veins, veins of trabecular bone and the venous spaces of erectile tissue. These veins consist of endothelium supported by variable amounts of connective tissue. Distinction between the media and adventitial layers is often difficult, and a discrete internal elastic lamina is absent.

Tethering of some veins to connective tissue fasciae and other surrounding tissues may prevent collapse of the vessel even under negative pressure. Pressure within the venous system does not normally exceed 5 mmHg, and it decreases as the veins grow larger and fewer in number, approaching zero close to the heart. Because they contain only a small amount of muscle, veins have limited influence on blood flow. However, during a sudden fall in blood pressure, e.g. following a haemorrhage, elastic recoil and reflex constriction in veins compensate for the blood loss and tend to maintain venous return to the heart. Vasoconstriction in cutaneous veins in response to cooling is important in thermoregulation.
Most veins have valves to prevent reflux of blood (Fig. 6.13, Fig. 6.14). A valve is formed by an inward projection of the intima, strengthened by collagen and elastic fibres, and covered by endothelium which differs in orientation on its two surfaces. Surfaces facing the vessel wall have transversely arranged endothelial cells, whereas on the luminal surface of the valve, over which the main stream of blood flows, cells are arranged longitudinally in the direction of flow. Most commonly two, or occasionally three, valves lie opposite one another, sometimes only one is present. They are found in small veins or where tributaries join larger veins. The valves are semilunar (cusps) and attached by their convex edges to the venous wall. Their concave margins are directed with the flow and lie against the wall as long as flow is towards the heart. When blood flow reverses, the valves close and blood fills an expanded region of the wall, a sinus, on the cardiac side of the closed valve. This may give a 'knotted' (varicose) appearance to the distended veins, if these have many valves. In the limbs, especially the legs where venous return is against gravity, valves are of great importance to venous flow. Blood is moved towards the heart by the intermittent pressure produced by contractions of the surrounding muscles. Valves are absent in veins of the thorax and abdomen.
Fig. 6.13 The upper portions of the femoral and long saphenous veins laid open to show the valves. About two-thirds of the natural size.
Fig. 6.14 A valve in a human small vein, formed from flap-like extensions of the intima which close when pressure increases on the proximal end, preventing backflow.
VASCULAR SHUNTS AND ANASTOMOSES

Arteriovenous shunts and anastomoses

Communications between the arterial and venous systems are found in many regions of the body. In some parts of the microcirculation (e.g. mesentery), the capillary circulation can be bypassed by wider thoroughfare channels formed by metarterioles (Fig. 6.15A). These have similarities to both capillaries and the smallest arterioles, and have a discontinuous layer of smooth muscle in their walls. Metarterioles can deliver blood directly to venules or to a capillary bed, according to local demand and conditions. When functional demand is low, blood flow is largely limited to the bypass channel. Periodic opening and closing of different arterioles irrigates different parts of the capillary network. The number of capillaries in individual microvascular units and the size of their mesh determine the degree of vascularity of a tissue: the smallest meshes occur in the lungs and the choroid of the eye.

Fig. 6.15  A, A microcirculatory unit, showing a terminal arteriole, thoroughfare channels, capillaries and collecting venule. The distribution of smooth muscle cells and one of the precapillary sites where perfusion of the capillary bed is regulated are also shown. B, An arteriovenous anastomosis. Note the thick wall of the anastomotic channel composed of layers of modified smooth muscle cells.

Arteriovenous anastomoses (Fig. 6.15B) are direct connections between smaller arteries and veins. Connecting vessels may be straight or coiled, and often possess a thick muscular tunic. Under sympathetic control, the vessel is able to close completely, diverting blood into the capillary bed. When patent, the vessel carries blood from artery to vein, partially or completely excluding the capillary bed from the circulation. Simple arteriovenous anastomoses are widespread and occur notably in
the skin of the nose, lips and ears, nasal and alimentary mucosae, erectile tissue, tongue, thyroid gland and sympathetic ganglia. In the newborn child, there are few arteriovenous anastomoses, but they develop rapidly during the early years. In old age they atrophy, sclerose and diminish in number. These factors may contribute to the less efficient temperature regulation which occurs at the two extremes of age.

In the skin of the hands and feet, especially in digital pads and nail beds (see Fig. 7.18), anastomoses form a large number of small units termed glomera. Each glomus organ has one or more afferent arteries, stemming from branches of cutaneous arteries which approach the surface. The afferent artery gives off a number of fine periglomeral branches and then immediately enlarges, makes a sinuous curve, and narrows again into a short funnel-shaped vein which opens at right angles into a collecting vein (Fig. 6.16).
Arterial anastomoses

Arteries can be joined to each other by an anastomosis, so that one can supply the territory of the other. An end-to-end anastomosis occurs when two arteries communicate directly, e.g. the uterine and ovarian arteries, the right and the left gastroepiploic arteries, the ulnar artery and the superficial palmar branch of the radial artery. Anastomosis by convergence occurs when two arteries converge and merge, as happens when the vertebral arteries form the basilar artery at the base of the brain. A transverse anastomosis occurs when a short arterial vessel links two large arteries transversely, e.g. the anastomoses between the two anterior cerebral arteries; the posterior tibial artery and the fibular artery; and the radial and ulnar arteries at the wrist.

The angiosome concept and vascular territories

An angiosome is a three-dimensional block of tissue (known as an anatomical territory) supplied by a source artery and its accompanying veins. It can be a composite of skin, underlying fascia, muscle and bone. These blocks of tissue form a complex three-dimensional jigsaw puzzle: some pieces have a predominantly cutaneous component while others are predominantly muscular. Each angiosome is made up of arteriosomes and venosomes and they are linked to neighbouring angiosomes by either simple anastomoses composed of similar calibre vessels or reduced calibre vessels termed choke vessels. The anastomoses between adjacent angiosomes can occur within the skin or within muscle. Some muscles are supplied by a single artery and its accompanying veins and therefore lie within one angiosome, while other muscles are supplied by more than one vessel and therefore cross more than one angiosome.

The clinical relevance of the angiosome concept is reflected in the potential connections of adjacent vascular territories. Should the source vessels for one angiosome become blocked or damaged, then that anatomical territory can be ‘rescued’ by receiving a blood supply from the immediately neighbouring angiosome via the connecting simple and choke vessel anastomoses. A detailed knowledge of angiosomes and vascular territories is essential for plastic and reconstructive
surgeons when designing and surgically raising flaps of tissue which can reliably be moved from one part of the body to another without disrupting their blood supply.
FUNCTIONAL MICROSTRUCTURE OF VESSELS

Intima

The intimal lining of blood vessels consists of an endothelium, and a variable amount of subendothelial connective tissue, depending on the vessel.

Endothelium

The endothelium is a monolayer of flattened polygonal cells which extends continuously over the luminal surface of the entire vascular tree (Fig. 6.17, see Fig. 6.10). Its structure varies in different regions of the vascular bed.

The endothelium is a key component of the vessel wall, and subserves several major physiological roles. Endothelial cells are in contact with the bloodstream and thus influence blood flow. They regulate the diffusion of substances and migration of cells out of and into the circulating blood. In the brain, endothelial cells of small vessels actively transport substances, e.g. glucose, into the brain parenchyma. Endothelial cells participate in the formation of blood clots (by secreting clot-promoting factors – von Willebrand factor); in minimizing clot formation (by secreting prostacyclin and thrombomodulin); and in the process of clot dissolution or fibrinolysis (by secreting tissue plasminogen activator). They have selective phagocytic activity and are able to extract substances from the blood. For example, the endothelium of pulmonary vessels removes and inactivates several polypeptides, biogenic amines, bradykinin, prostaglandins and lipids from the circulation. Endothelial cells secrete both vasoconstrictive (thromboxane) and vasodilator (prostacyclin) prostaglandins, nitric oxide (NO, relaxing factor) and endothelin (a vasoconstrictor), which affect the tone of smooth muscle in vessel walls. They are sensitive to stretch (e.g. increased pressure) and the shear effect of blood flow, via stretch-sensitive ion channels in the cell membrane. Endothelial cells synthesize components of the basal lamina. They proliferate to provide new cells during the growth in size of a blood vessel, to replace damaged endothelial cells, and to provide solid cords of cells which develop into new blood vessels (angiogenesis). Angiogenesis, which may be stimulated by endothelial production of autocrine growth factors (see Ch. 1) in response to locally low oxygen tension, is important in wound healing, and in the growth of tumours. Endothelial cells are also active participants in, and regulators of, inflammatory processes (reviewed in Pober & Sessa, 2007).

Endothelial cells are thin but extend over a relatively large surface area. They are generally elongated in the direction of blood flow, especially in arteries (see Fig. 6.17). They usually adhere firmly to each other at their edges, so that the lining of the lumen presents no discontinuity, other than in sinusoids. The thickness of endothelial cells is maximal at the level of their nucleus, where it can reach 2–3 µm, and this part of the cell often bulges slightly into the lumen (see Fig. 6.10). Elsewhere, the endothelial cell is thinner and laminar: in capillaries, these portions of the cell often measure as little as 0.2 µm in thickness.

Transcytotic (pinocytotic) vesicles (see Fig. 6.11) are present in all endothelial cells, but are particularly numerous in exchange vessels; they include caveolae (see Fig. 6.4) typical of smooth muscle cells. They shuttle small amounts of extracellular fluid or blood plasma across the endothelial cytoplasm and thus facilitate the bulk exchange
of dissolved gases, nutrients and metabolites between these compartments. In spite of the factors known to be released by endothelial cells, they do not have the morphological characteristics of secretory cells.

An organelle which characterizes endothelial cells is the Wiebel–Palade body, an elongated cytoplasmic vesicle, $0.2 \times 2–3 \mu m$ in length, which contains regularly spaced tubular structures parallel to its long axis. Wiebel–Palade bodies store the adhesion molecule, P-selectin, and a large glycoprotein known as von Willebrand factor, which is released into the subendothelial connective tissue; it mediates the binding of platelets to the extracellular matrix and platelet aggregation, after vascular injury. Von Willebrand factor is also produced by megakaryocytes and is stored in platelets. Plasma von Willebrand factor binds factor VIII clotting protein, which is secreted into the bloodstream by hepatocytes. Hereditary deficiency or defective function of von Willebrand factor causes a clotting disorder of the same name.

Endothelial cells adhere to adjacent cells through the junctional complex, an area of apposition where adherent and tight junctions are found. They also communicate via gap junctions. Tight junctions are most marked in continuous capillaries. Cell contacts between endothelial cells and smooth muscle cells are common in arterioles, where the separation between endothelium and media is reduced and the inner elastic lamina is either very thin or absent.

**Endothelial–leukocyte interactions**

The luminal surface of endothelial cells does not normally support the adherence of leukocytes or platelets. However, many functions of human vascular endothelial cells are dynamic rather than fixed. Activated endothelial cells and the characteristic endothelium of high endothelial venules (HEV) of lymphoid tissues, are sites of leukocyte attachment and diapedesis (see below).

HEV (Fig. 6.18) are located within the T cell domains, between and around lymphoid follicles in all secondary lymphoid organs and tissues except the spleen. They are specialized venules of 7–30 µm diameter, which possess a conspicuous cuboidal endothelial lining. The luminal aspect of HEVs shows a cobblestone appearance. The endothelial cells rest on a basal lamina and are supported by pericytes and a small amount of connective tissue (Fig. 6.19). They are linked by discontinuous adhesive junctions at their apical and basal aspects: the junctions are circumnavigated by migrating lymphocytes. Ultrastructurally, the endothelial cells have the characteristics of metabolically active secretory cells. They contain large, rounded euchromatic nuclei with one or two nucleoli, prominent Golgi complexes, many mitochondria, ribosomes and pinocytotic vesicles. Typically, they also possess Wiebel–Palade bodies (see above).

Many of the adhesion molecules which mediate interactions between blood leukocytes and HEVs or cytokine-activated endothelium have been identified. They can be divided into three general families: selectins, integrins and the immunoglobulin supergene family. Selectins and integrins are expressed on leukocytes and mediate adhesion of circulating cells to the endothelium, which expresses selectins and members of the immunoglobulin supergene family. Regulated expression of these molecules by both cell types provides the means by which leukocytes recognize the vessel wall (leukocyte homing antigens and vascular addressins), adhere to it and
subsequently leave the circulation.

The first step in this cascade is the loose binding or tethering of leukocytes, and is initiated via L-, P- or E-selectin (see below). This weak, reversible adhesion allows leukocytes to roll along the endothelial surface of a vessel lumen at low velocity, making and breaking contact, and sampling the endothelial cell surfaces. Recognition of chemokines (chemotactic signalling molecules) presented by the endothelium leads to ‘inside-out’ signalling and conversion of integrins at the leukocyte surface into actively adhesive configurations which bind strongly to their endothelial ligands, resulting in stable arrest. Finally, the leukocyte migrates through the vessel wall (diapedesis), passing between (paracellular migration) or across (transcellular migration) endothelial cells. It is now thought that transcellular migration is the preferred pathway and endothelial transcytotic vesicles (caveolae), intermediate filaments (vimentin) and F-actin are important in the creation of transient transcellular channels through which leukocytes pass. They then cross the basal lamina and migrate into the surrounding tissue by mechanisms which involve CD31 antigen and matrix metalloproteinases (see Ch. 2).

Cell adhesion molecules

Three members of the selectin family of adhesive proteins are currently recognized. They are L-selectin (also known as lymphocyte homing receptor), E-selectin and P-selectin. L-selectin is expressed on most leukocytes. Endothelial cells of HEVs in lymphoid organs express its oligosaccharide ligand, although other molecules such as mucins may be alternative ligands. Thus, L-selectin mediates homing of lymphocytes, especially to peripheral lymph nodes, but also promotes the accumulation of neutrophils and monocytes at sites of inflammation. E-selectin is an inducible adhesion molecule which mediates adhesion of leukocytes to inflammatory cytokine-activated endothelium, and is only transiently expressed on endothelium. P-selectin is rapidly mobilized from Wiebel–Palade bodies, where it is stored, to the endothelial surface after endothelial activation. It binds to ligands expressed on neutrophils, platelets, and monocytes and, like E-selectin, tethers leukocytes to endothelium at sites of inflammation. However, since P-selectin is quickly endocytosed by the endothelial cells, its expression is short-lived.

The integrins are a large family of molecules which mediate cell-to-cell adhesion as well as interactions of cells with extracellular matrix. Certain $\beta$-1 integrin heterodimers are expressed on lymphocytes 2–4 weeks after antigenic stimulation (very late antigens, VLA), and bind to the extracellular matrix. Additionally, VLA-4 present on resting lymphocytes (the expression of which increases after activation), monocytes and eosinophils, binds to the vascular cell adhesion molecule-1 (VCAM-1), the ligand on activated endothelium. In contrast to $\beta$-1 integrins, which many cells express, the expression of $\beta$-2 integrins is limited to white blood cells. Although the leukocyte integrins are not constitutively adhesive, they become highly adhesive after cell activation and therefore play a key role in the events required for cell migration. The endothelial ligands for one such $\beta$-2 integrin are the intercellular adhesion molecules-1 and -2 (ICAM-1 and ICAM-2), which belong to the immunoglobulin superfamily.

Three members of the large immunoglobulin superfamily of proteins are involved in leukocyte-endothelial adhesion, providing integrin counter-receptors on the endothelial cell membrane. ICAM-1 and ICAM-2 are constitutively expressed but
upregulated by inflammatory cytokines. VCAM-1 is absent from resting endothelium but is induced by cytokines on activated endothelium and promotes extravasation of lymphocytes at sites of inflammation.

Subendothelial connective tissue

The subendothelial connective tissue, also termed the lamina propria, is a thin but variable layer. It is largely absent in the smallest vessels, where the endothelium is supported instead by pericytes (see Fig. 6.21). It contains a typical fibrocollagenous extracellular matrix, a few fibroblasts and occasional smooth muscle cells. Endothelial von Willebrand factor concentrates in this layer and participates in the clotting process when the overlying endothelium is damaged.

Media

The media consists chiefly of concentric layers of circumferentially or helically arranged smooth muscle cells with variable amounts of elastin and collagen.

Smooth muscle

Smooth muscle forms most of the media of arteries (see Fig. 6.8) and arterioles. A thinner layer of smooth muscle is also found in venules and veins, with the exception of small segments of the pulmonary veins, where striated cardiac muscle is present in the portions nearest to the heart. Contraction of the smooth muscle in arteries and arterioles reduces the calibre of the vessel lumen, which reduces blood flow through the vessel and raises the pressure on the proximal side. This role is particularly effective in small resistance vessels where the wall is thick, relative to the diameter of the vessel. Smooth muscle can also alter the rigidity of the wall, without causing constriction (isometric contraction), and this affects the distensibility of the wall and propagation of the pulse.

The smooth muscle cells synthesize and secrete elastin, collagen and other extracellular components of the media which bear directly on the mechanical properties of the vessels. The mechanics of the musculature of the media are complex. Distensibility, strength, self-support, elasticity, rigidity, concentric constriction etc., are interrelated functions and are finely balanced in the different regions of the vascular bed.

In large arteries, where the blood pressure is high, the muscle cells are shorter (60–200 µm) and smaller in volume than in visceral muscle. In arterioles and veins, smooth muscle cells more closely resemble visceral muscle cells. The cells are packed with myofilaments and other elements of the cytoskeleton, including intermediate filaments. Vascular muscle cells have intermediate filaments of either vimentin alone or both vimentin and desmin; the intermediate filaments of visceral smooth muscle are exclusively of desmin. Intercellular junctions are mainly of the adhesive (adherens) type and provide mechanical coupling between the cells. In addition, there are gap (communicating) junctions which couple cells electrically. Junctions between muscle cells and the connective tissue matrix are particularly numerous, especially in arteries.

The muscle cells of the arterial media can be regarded as multifunctional mesenchymal cells. After damage to the endothelium, muscle cells migrate into the
intima and proliferate, forming bundles of longitudinally oriented cells which reform the layer. In certain pathological conditions, muscle cells (and macrophages) undergo fatty degeneration and participate in the formation of atheromatous plaques.

Collagen and elastin

Components of the extracellular matrix are major constituents of vessel walls, and in large arteries and veins they make up more than half of the mass of the wall, mainly in the form of collagen and elastin. Other fibrous components such as fibronectin, and amorphous proteoglycans and glycosaminoglycans, are present in the interstitial space.

Elastin is found in all arteries and veins and is especially abundant in elastic arteries (see Fig. 6.6). Individual elastic fibres (0.1–1.0 µm in diameter) anastomose with each other to form net-like structures, which extend predominantly in a circumferential direction. More extensive fusion produces lamellae of elastic material, which though usually perforated and thus incomplete, separate the layers of muscle cells. A conspicuous elastic lamella, the internal elastic lamina, is seen in arteries, between intima and media. This is a tube of elastic material which allows the vessel to recoil after distension. When the intraluminal pressure falls below physiological limits (postmortem), the inner elastic lamina is compressed and it coils up into a regular corrugated shape (Fig. 6.20, see Figs 6.8, 6.10): in these conditions the lumen is much reduced but is not obliterated, and the profile of the artery remains circular. Fenestrations in the elastic lamina, which may also be split in thickness, allow materials to diffuse between intima and media. An outer elastic lamina, similar in appearance to, but markedly less well developed and less compact than the internal elastic lamina, lies at the outer aspect of the media at its boundary with the adventitia (see Fig. 6.8). These laminae are less evident in elastic arteries, where elastic fibres occupy much of the media (see Fig. 6.6).
Collagen fibrils are found in all three vessel layers. Type III collagen (reticulin) occupies much of the interstitial space between the muscle cells of the media, and is also found in the intima. Collagen is abundant in the adventitia, where type I collagen fibres form large bundles which increase in size from the junction with the media to the outer limit of the vessel wall. In veins, collagen is the main component of the vessel wall, and accounts for more than half its mass.

In general terms, collagen and elastic fibres in the media run parallel to, or at a small angle to, the axes of the muscle cells, and they are therefore mainly circumferentially arranged. In contrast, the predominant arrangement of collagen fibres in the adventitia is longitudinal. This arrangement imposes constraints on length change in large vessels under pressure, e.g. in large arteries, in which the radial distension under the effect of the pulse far exceeds the longitudinal distension. The outer sheath of type I collagen in the adventitia therefore has a structurally supportive role. The more delicate type III collagen network of the media provides attachment to the muscle cells and its role is to transmit force around the circumference of the vessel. In a distended vessel, the elastic fibres store energy and, by recoiling, help to restore the resting length and calibre.

The extracellular material of the media, including collagen and elastin, is produced by the muscle cells. Its turnover is slow compared to that in other tissues. In the adventitia, collagen is synthesized and secreted by fibroblasts, as in other connective tissues. During postnatal development, while vessels increase in diameter and wall thickness, there is an increase in elastin and collagen content. Subsequent changes
in vessel structure, seen during ageing, include an increase in the collagen-to-elastin ratio, with a reduction in vessel elasticity.

**Adventitia**

The adventitia is formed of general connective tissue, varying in the thickness and density of its collagen fibre bundles.

**Vasa vasorum**

In smaller vessels, the nourishment of the tissues of the vessel wall is provided by diffusion from the blood circulating in the vessel itself. Large vessels have their own vascular supply within the adventitia (see Figs 6.7, 6.8), in the form of a network of small vessels, mainly of the microcirculation, which are called the vasa vasorum. The wall thickness at which simple diffusion from the lumen becomes insufficient is 1 mm.

The vasa vasorum originate from, and drain into, adjacent vessels which are peripheral branches of the vessel they supply. They ramify within the adventitia and, in the largest of arteries, penetrate the outermost part of the media. The larger veins are also supplied by vasa vasorum, but these may penetrate the wall more deeply, perhaps because of the lower oxygen tension.

**Nervi vasorum**

Blood vessels are innervated by efferent autonomic fibres which regulate the state of contraction of the musculature (muscular tone), and thus the diameter of the vessels, particularly the arteries and arterioles. These perivascular nerves branch and anastomose within the adventitia of an artery, forming a meshwork around it. In some of the large muscular arteries, nerves are occasionally found within the outermost layers of the media.

Nervi vasorum are small bundles of axons, which are almost invariably unmyelinated and typically varicose. Most are postganglionic fibres which issue from sympathetic ganglion neurones. Some vessels in the brain may be innervated by intrinsic cerebral neurones although neural control of brain vessels is of minor importance compared with metabolic and autoregulation (local response to stretch stimuli). The density of innervation varies in different vessels and in different areas of the body: it is usually sparser in veins and larger lymphatic vessels. Large veins with a pronounced muscle layer, such as the hepatic portal vein, are well-innervated.

The control of vascular smooth muscle is complex. Vasoconstrictor adrenergic fibres release noradrenaline (norepinephrine) which acts on adrenoceptors in the muscle cell membrane. In addition, circulating hormones and factors such as nitric oxide and endothelins, which are released from endothelial cells, exert a powerful effect on the muscle cells. The neurotransmitters reach the muscle from the adventitial surface of the media, and hormonal and endothelial factors diffuse from the intimal surface. In some tissues, sympathetic cholinergic fibres inhibit smooth muscle contraction and induce vasodilation.

Most arteries are accompanied by nerves which travel in parallel with them to the peripheral organs which they supply. However, these paravascular nerves are quite independent, and do not innervate the vessels they accompany.
**Pericytes**

Pericytes are present at the outer surface of capillaries and the smallest venules (postcapillary venules), where an adventitia is absent and there are no muscle cells. They are elongated cells, whose long cytoplasmic processes are wrapped around the endothelium. Pericytes are scattered in a discontinuous layer around the outer circumference of capillaries. They are generally absent from fenestrated capillaries, but form a more continuous layer around postcapillary venules (Fig. 6.21). They are gradually replaced by smooth muscle cells as vessels converge and increase in diameter.

Pericytes are enclosed by their own basal lamina, which merges in places with that of the endothelium. Most pericytes display areas of close apposition with endothelial cells, and occasionally form adherens junctions where their basal laminae are absent. Pericyte cytoplasm contains actin, myosin, tropomyosin and desmin, which suggests that these cells are capable of contractile activity. They also have the potential to act as mesenchymal stem cells, and they participate in repair processes by proliferating and giving rise to new blood vessel and connective tissue cells.

**Cerebral vessels**

Major branches of cerebral arteries that lie in the subarachnoid space over the surface of the brain have a thin outer coating of meningeal cells, usually one layer thick, where adjacent meningeal cells are joined by desmosomes and gap junctions. These arteries have a smooth muscle media and a distinct elastic lamina. Veins on the surface of the brain have very thin walls, and the smooth muscle layers in the wall are often discontinuous. They are coated externally by a monolayer of meningeal cells.

As arteries enter the subpial space and penetrate the brain, they lose their elastic laminae, and consequently the cerebral cortex and white matter typically contain only arterioles, venules and capillaries. The exceptions are the large penetrating vessels in the basal ganglia, where many arteries retain their elastic laminae and thick smooth muscle media. Enlarged perivascular spaces form around these large arteries in ageing individuals. Arterioles and venules in the cortex and white matter can be distinguished from each other because arterioles are surrounded by a smooth muscle coat, and the veins and venules have larger lumina and thinner walls.

Cerebral capillaries are the site of the blood–brain barrier (p. 49). They are lined by endothelial cells which are joined by tight junctions. The endothelial cytoplasm contains a few pinocytotic vesicles. The cells are surrounded by a basal lamina (see Fig. 3.13): at points of contact with perivascular astrocytes the intervening basal lamina is formed by fusion of the endothelial and glial basal laminae. Pericytes, completely surrounded by basal lamina, are present around capillaries. Perivascular macrophages are attached to the outer walls of capillaries and to other vessels: they are phenotypically distinct from parenchymal microglia, which are also of monocytic origin. A thin layer of meningeal cells derived from the pia mater surrounds arterioles but disappears at the level of capillaries. For further descriptions of cerebral vessels, see Ch. 17.
LYMPHATIC VESSELS

Lymphatic capillaries form wide-meshed plexuses in the extracellular matrices of most tissues. They begin as dilated, blind-ended tubes with larger diameters and less regular cross-sectional appearances than those of blood capillaries. A basal lamina is incomplete or absent and they lack associated pericytes. The smaller lymphatic vessels are lined by endothelial cells, which have numerous transcytotic vesicles within their cytoplasm, and so resemble blood capillaries. However, unlike capillaries, their endothelium is generally quite permeable to much larger molecules; they are readily permeable to large colloidal proteins and particulate material such as cell debris and microorganisms, and also to cells. Permeability is facilitated by gaps between the endothelial cells, which lack tight junctions, and by pinocytosis.

Lymph is formed from interstitial fluid, which is derived from blood plasma via the microcirculation. Much of this fluid is returned to the venous system. Lymphatic vessels take up residual fluid (about one tenth) by passive diffusion and the transient negative pressures in their lumina which are generated intrinsically by contractile activity of smooth muscle in the largest lymphatic vessel walls, and extrinsically, by movements of other tissues (muscles, arteries) locally. The unidirectional flow of lymph is maintained by the presence of valves in the larger vessels (see Fig. 6.22). Lymphatic capillaries are prevented from collapsing by anchoring filaments which tether their walls to surrounding connective tissue structures and exert radial traction.
In most tissues, lymph is clear and colourless. In contrast, the lymph from the small intestine is dense and milky, reflecting the presence of lipid droplets (chylomicrons) derived from fat absorbed by the mucosal epithelium. The terminal lymphatic vessels in the mucosa of the small intestine are known as lacteals and the lymph as chyle. Lymphatic capillaries are not ubiquitous: they are not present in cornea, cartilage, thymus, the central or peripheral nervous system or bone marrow, and there are very few in the endomysium of skeletal muscles.

Lymphatic capillaries join into larger vessels which pass to local lymph nodes. Typically, lymph percolates through a series of nodes before reaching a major collecting duct. There are exceptions to this arrangement: the lymph vessels of the thyroid gland and oesophagus, and of the coronary and triangular ligaments of the liver, all drain directly to the thoracic duct without passing through lymph nodes. In the larger vessels, a thin external connective tissue coat supports the endothelium. The largest lymphatic vessels (200 µm) have three layers, like small veins, although their lumen is considerably larger than is the case in veins with a similar wall thickness. The tunica media contains smooth muscle cells, mostly arranged circumferentially. Elastic fibres are sparse in the tunica intima, but form an external elastic lamina in the tunica adventitia.

The larger lymphatic vessels differ from small veins in having many more valves (Fig. 6.22). The valves are semilunar, generally paired and composed of an extension of the intima. Their edges point in the direction of the current, and the vessel wall downstream is expanded into a sinus, which gives the vessels a beaded appearance when they are distended. Valves are important in preventing the backflow of lymph.

Deep lymphatic vessels usually accompany arteries or veins, and almost all reach either the thoracic duct or the right lymphatic duct, which usually join the left or right brachiocephalic veins respectively at the root of the neck.

The thoracic duct is structurally similar to a medium-sized vein, but the smooth muscle
in its tunica media is more prominent. Most lymphatic vessels anastomose freely, and larger ones have their own plexiform vasa vasorum and accompanying nerve fibres. If their walls are acutely infected (lymphangitis) this vascular plexus becomes congested, marking the paths of superficial vessels by red lines, which are visible through the skin, and tender to the touch.

Lymphatic vessels repair easily and new vessels readily form after damage. They begin as solid cellular sprouts from the endothelial cells of persisting vessels and later become canalized.
CARDIAC MUSCLE

In cardiac muscle, as in skeletal muscle, the contractile proteins are organized structurally into sarcomeres which are aligned in register across the fibres, producing fine cross-striations that are visible in the light microscope. They both contain the same contractile proteins (although many are cardiac isoforms), which are assembled in a similar way, and the molecular basis for contraction, but not its regulation, is the same. Release of calcium into the sarcoplasm triggers contraction, which corresponds to cardiac systole, the pumping phase of the heart cycle. Reuptake of calcium produces relaxation, which corresponds to cardiac diastole, the filling phase of the cycle.

Despite the similarities, there are major functional, morphological and developmental differences between cardiac and skeletal muscle. Some of the ways in which cardiac muscle differs morphologically from skeletal muscle are described below, before consideration of other features that are unique to cardiac muscle.

MICROSTRUCTURE

The myocardium, the muscular component of the heart, constitutes the bulk of its tissues. It consists predominantly of cardiac muscle cells, which are usually 120 µm long and 20–30 µm in diameter in a normal adult. Each cell has one or two large nuclei, occupying the central part of the cell, whereas skeletal muscle has multiple, peripherally placed nuclei. The cells are branched at their ends, and the branches of adjacent cells are so tightly associated that the light microscopic appearance is of a network of branching and anastomosing fibres (Fig. 6.23). Cells are bound together by elaborate junctional complexes, the intercalated discs (Fig. 6.23, Fig. 6.24, see Fig. 6.26).
Fig. 6.23 Cardiac muscle fibres (human heart), sectioned longitudinally. Faint fine cross-striations are just visible (arrow) and indicate the intracellular organization of sarcomeres. The darker transverse lines (some appear stepped) are intercalated discs (D). Endomysium (E) contains nuclei of endothelial cells and macrophages.
Fig. 6.24 Three-dimensional reconstruction of cardiac muscle cells in the region of an intercalated disc, a junctional complex between neighbouring cells. The interdigitating transverse parts of the intercalated disc form a fascia adherens, with numerous desmosomes; gap junctions are found in the longitudinal parts of the disc. The organization of the transverse tubules and sarcoplasmic reticulum is also shown.
Fine fibrocollagenous connective tissue is found between cardiac muscle fibres. Although this is equivalent to the endomysium of skeletal muscle, it is less regularly organized because of the complex three-dimensional geometry imposed by the branching cardiac cells. Numerous capillaries and some nerve fibres are found within this layer. Coarser connective tissue, equivalent to the perimysium of skeletal muscle, separates the larger bundles of muscle fibres, and is particularly well developed near the condensations of dense fibrous connective tissue that form the ‘skeleton’ of the heart (see Ch. 56). The ventricles of the heart are composed of spiralling layers of fibres which run in different directions. Consequently, microscope sections of ventricular muscle inevitably contain the profiles of cells cut in a variety of orientations. A linear arrangement of cardiac muscle fibres is found only in the papillary muscles and trabeculae carneae.

Electron micrographs of cardiac muscle cells in longitudinal section (Fig. 6.25) show that the myofibrils separate before they pass around the nucleus, leaving a zone that is occupied by organelles, including sarcoplasmic reticulum, Golgi complex, mitochondria, lipid droplets, and glycogen. At the light microscopic level, these zones
appear in longitudinal sections as unstained areas at the poles of each nucleus. They often contain lipofuscin granules, which accumulate there in individuals over the age of 10; the reddish-brown pigment may be visible even in unstained longitudinal sections.

Fig. 6.25 Low power electron micrograph of cardiac muscle in longitudinal section, including the perinuclear zone of one of the fibres. Note the abundant large mitochondria (M) between myofibrils (My), and an intercalated disc (circled). By courtesy of Professor Brenda Russell, Department of Physiology and Biophysics, University of Illinois at Chicago.)

The cross-striations of cardiac muscle are less conspicuous than those of skeletal muscle. This is because the contractile apparatus of cardiac muscle lies within a mitochondria-rich sarcoplasm. The myofibrils are less well delineated than they are in skeletal muscle: in transverse sections they often fuse into a continuous array of
myofilaments, irregularly bounded by mitochondria and longitudinal elements of sarcoplasmic reticulum. The large mitochondria, with their closely spaced cristae, reflect the highly developed oxidative metabolism of cardiac tissue. The proportion of the cell volume occupied by mitochondria (approximately 35%) is even greater in cardiac muscle than it is in slow twitch skeletal muscle fibres. The high demand for oxygen is also reflected in high levels of myoglobin and an exceptionally rich network of capillaries around the fibres.

The force of contraction is transferred through the ends of the cardiac muscle cells via the junctional strength provided by the intercalated discs. As in skeletal muscle, force is also transmitted laterally to the sarcolemma and extracellular matrix via vinculin-containing elements which bridge between the Z-discs of peripheral myofibrils and the plasma membrane.

Atrial muscle cells are smaller than ventricular cells. The cytoplasm near the Golgi complexes at the poles of the nuclei exhibits dense membrane-bound granules, which contain the precursor of atrial natriuretic factor. This is a hormone whose action is to promote loss of sodium chloride and water in the kidneys, reducing body fluid volume and thereby lowering blood pressure. It is released in response to stretch of the atrial wall. The actions of atrial natriuretic factor are normally balanced by the opposing effects of aldosterone and antidiuretic hormone.

The sarcolemma of ventricular cardiac muscle cells invaginates to form T-tubules with a wider lumen than those of skeletal muscle; atrial muscle cells have few or no T-tubules. Unlike skeletal muscle, most T-tubules penetrate the sarcoplasm at the level of the Z-discs (Fig. 6.24). The T-tubules are interconnected at intervals by longitudinal branches to form a complex network. They probably serve a similar function in skeletal and cardiac muscle, i.e. to carry the wave of depolarization into the core of the cells. The actin-binding proteins, spectrin and dystrophin, are important components of the cardiac muscle cell cytoskeleton, which associate independently with the sarcolemma to provide mechanical support.

The sarcoplasmic reticulum is a membrane-bound tubular plexus which surrounds, and defines, sometimes incompletely, the outlines of individual myofibrils. Its main role, as in skeletal muscle, is the storage, release and reaccumulation of calcium ions. It comes into close contact with the T-tubules, leaving a 15 nm gap that is spanned by structures termed junctional processes. These processes are thought to be the cytoplasmic part of the calcium release channels (ryanodine receptors); similar processes are found in skeletal muscle at the junctional surface of the terminal cisternae. Sarcoplasmic reticulum which bears junctional processes has been termed junctional sarcoplasmic reticulum, to distinguish it from the free sarcoplasmic reticulum, which forms a longitudinal network. Junctional sarcoplasmic reticulum makes contact with both the T-tubules and the sarcolemma (of which the T-tubules are an extension). Sarcoplasmic reticulum forms small globular extensions (corbular sarcoplasmic reticulum) in the vicinity of the Z-discs, but not in immediate relation to T-tubules or the sarcolemma. Since the junctions between T-tubules and sarcoplasmic reticulum usually involve only one structure of each type, the corresponding profiles in electron micrographs are referred to as dyads, rather than triads as in skeletal muscle.
Intercalated discs are unique to cardiac muscle. In the light microscope they are seen as transverse lines crossing the tracts of cardiac cells (see Fig. 6.23). They may step irregularly within or between adjacent tracts, and may appear to jump to a new position as the plane of focus is altered. At the ultrastructural level these structures, which are complex junctions between the cardiac muscle cells, are seen to have transverse and lateral portions (see Fig. 6.24, Fig. 6.26). The transverse portions occur wherever myofibrils abut the end of the cell, and each takes the place of the last Z-disc. At this point, the actin filaments of the terminal sarcomere insert into a dense subsarcolemmal matrix which anchors them, together with other cytoplasmic elements such as intermediate filaments, to the plasma membrane. Prominent desmosomes, often with a dense line in the intercellular space, occur at intervals along each transverse portion. This junctional region is homologous with, and probably similar in composition to, the structure found on the cytoplasmic face of the myotendinous junction, and is a type of fascia adherens junction. It provides firm adhesion between cells, and a route for the transmission of contractile force from one cell to the next.

The lateral portions of the intercalated disc run parallel to the myofilaments, and the long axis of the cell, for a distance which corresponds to one or two sarcomeres before it turns again to form another transverse portion. It is therefore responsible for the stepwise progression of the intercalated disc which can be seen microscopically. The lateral portions contain gap junctions, which are responsible for the electrical coupling between adjacent cells (see Fig. 6.26). Conductance channels within these junctions enable the electrical impulse to propagate from one cell to the next, spreading excitation and contraction rapidly along the branching tracts of interconnected cells. In this way the activity of the individual cells of the heart is coordinated so that they function as if they were a syncytium.
The activity of the heart is equivalent to a constant power expenditure of 1.3 watts under basal conditions, and escalates to 3 watts or more during physical exertion. Cardiac muscle cells contain glycogen, which is a reserve during peaks of activity, but the majority of their energy requirement is continuous and supplied only through a highly developed oxidative metabolism, as is evident from the high proportion of the cell volume which is occupied by mitochondria. This metabolism has to be supported by a rich blood supply. Myocardium has a very high perfusion rate of 0.5 ml/min/g of tissue (five times that of liver and 15 times that of resting skeletal muscle). No cardiac muscle cell is more than 8 µm from a capillary, and vascular channels occupy a high proportion of the total interstitial space. Heart muscle is supplied by the coronary vessels. Although there is some variation in the detailed distribution of the arterial branches, the left ventricle, which has the highest workload, consistently receives the highest arterial blood flow. Branches run in the myocardium along the coarser aggregations of connective tissue and ramify extensively in the endomysial layer, creating a rich plexus of anastomosing vessels. This plexus includes lymphatic as well as blood capillaries, which is not the case in skeletal muscle.

The high oxygen requirement of the myocardium makes it vulnerable to ischaemic damage arising from atheroma or embolism in the coronary arteries. Arterial anastomoses, often more than 100 µm in diameter, are found throughout the heart and are an important factor in determining whether an adequate collateral circulation can develop after a coronary occlusion.
INNERVATION

Although the impulse-generating and conducting system of the heart establishes an endogenous rhythm, the rate and force of contraction are under neural influence. Both divisions of the autonomic nervous system supply non-myelinated postganglionic fibres to the heart. The innervation is derived bilaterally, but it is functionally asymmetrical. Activation of the left stellate ganglion (sympathetic) has little effect on heart rate but increases ventricular contractility, whereas activation of the right stellate ganglion influences both rate and contractility. Activation of the right vagus nerve (parasympathetic) slows heart rate mainly through its influence on the pacemaker region, the sinoatrial (SA) node, whereas activation of the left vagus slows propagation of the impulse mainly through its effect on the atrioventricular (AV) node. Vagal activity has little direct effect on ventricular contractility.

Sympathetic nerve fibres from the cervical sympathetic ganglia reach the heart via the cardiac nerves. Parasympathetic fibres in the heart originate in ganglion cells that are innervated by efferent fibres of the vagus nerve. Adrenergic, cholinergic and peptidergic endings have been demonstrated in the myocardium. Fibres often end close to muscle cells and blood vessels, but junctional specializations are not seen, and a gap of at least 100 nm remains between cell and nerve fibre. It is probable that neurotransmitters diffuse across this gap to the adjacent cells. Some of the endings represent efferent nerve terminals, others function as pain, mechano- or chemoreceptors.
EXCITATION–CONTRACTION COUPLING IN CARDIAC MUSCLE

The molecular interaction between actin and myosin that underlies the generation of force is initiated in the same way in cardiac and skeletal muscle. However, differences in the physical arrangement and molecular composition of these contractile elements have a profound influence on contractile function in cardiac muscle.

The calcium release channels of the sarcoplasmic reticulum are sensitive to the concentration of free calcium in the gap between the T-tubule and sarcoplasmic reticulum membranes. This underlies ‘calcium-induced calcium release’, which is believed to be the principal, and probably the only, mechanism involved in the liberation of calcium from the sarcoplasmic reticulum during physiological activation. The passage of an action potential depolarizes the sarcolemma and thereby opens sarcolemmal L-type calcium channels, which allows some calcium to enter from the extracellular space. This produces a localized rise in the intracellular free calcium concentration near the calcium release channels, which consequently open, allowing calcium ions to flow down their concentration gradient from the sarcoplasmic reticulum into the cytosol. The rise in cytosolic calcium concentration then activates the contractile machinery.

Systolic activation is terminated by reuptake of calcium from the cytosol. Although both the sarcolemma and the mitochondrial membrane have some capacity for calcium transport, the main route of uptake is into the sarcoplasmic reticulum, via a high-affinity, calcium-transporting ATPase. The activity of this ATPase controls the rate of decay of the calcium transient and is therefore a determinant of the rate of relaxation of the heart. The sarcoplasmic reticulum contains a cardiac form of calsequestrin, a distant homologue of the protein found in skeletal muscle. This calcium-binding protein buffers the free calcium concentration inside the sarcoplasmic reticulum, allowing it to store considerable amounts of total calcium without increasing the gradient against which the calcium-ATPase must pump.

One of the major functional differences between cardiac and skeletal muscle is the way in which contractile force is regulated. Smoothness and gradation of contraction in a skeletal muscle depend on the recruitment and asynchronous firing of different numbers of motor units. Individual motor units can also build up a contraction through a brief series of re-excitations. In the heart, the entire mass of muscle must be activated almost simultaneously, and mechanical summation by re-excitation is not possible, because the cells are electrically refractory until mechanical relaxation has taken place.

In cardiac muscle cells, as in skeletal muscle cells, contraction is initiated when calcium binds to troponin-C, a component of the regulatory protein complex on the thin filaments. During basal activity of the heart, the amount
of calcium bound to troponin-C during each systole induces less than half-maximal activation of the contractile apparatus. There is therefore the potential for producing more force by increasing the amount of calcium bound to troponin-C. This can be achieved by controlling the amount of free calcium that is released into the cytosol during systole.

A special feature of the cardiac cell is the long duration of its action potential. The long-lasting plateau of depolarization allows a prolonged inward flux of calcium to take place via the L-type calcium channels in the sarcolemma. During the relaxation phase, the calcium is actively pumped into the sarcoplasmic reticulum: the extent to which the sarcoplasmic reticulum is loaded is crucially dependent on this entry of extracellular calcium. The greater the amount of calcium that is stored in the sarcoplasmic reticulum, the more is available for release during subsequent contractions. These calcium movements provide an automatic mechanism for matching any increase in heart rate with a progressive increase in contractile force. At higher heart rates, more calcium enters per unit time and is pumped into the sarcoplasmic reticulum. Each systole is then more forceful, because the amount of calcium that can be delivered into the cytosol is greater.

The most potent physiological means of enhancing cardiac contractility is through the action of β-adrenergic agents, such as adrenaline (epinephrine) and noradrenaline (norepinephrine). These increase calcium taken up by the sarcoplasmic reticulum in two ways. Firstly, β-adrenergic stimulation increases the amount of calcium that enters during depolarization by opening more L-type calcium channels. Secondly, β-adrenergic stimulation can enhance the activity of the calcium-pumping ATPase by phosphorylating an associated protein, phospholamban. This enables the calcium pump to lower the cytosolic free calcium more rapidly, which contributes to the accelerated relaxation produced by β-adrenergic agonists. In a coordinated manner, phosphorylation of troponin-I on the thin filament increases the rate of cross-bridge cycling to aid the acceleration of relaxation.

Because of the clinical significance of positive inotropic agents (substances which increase the strength of cardiac contraction), generally now used only in severe end-stage heart failure, there is great interest in the multiple control sites which might provide targets for pharmacological intervention. Some of these are related to another important set of ionic fluxes through the sarcolemma via the sodium–potassium pump and the bidirectional sodium–calcium exchange and sodium-hydrogen exchange transporter proteins.
Cardiac myocytes differentiate from the splanchnic coelomic cells of the pericardium initially subjacent to the endoderm. Myogenic activity begins at the beginning of stage 10, 22 days gestation, when the embryo has four somites. At this time the presumptive cardiac myocytes express myosin, actin, troponin and other contractile proteins. The cardiac myocytes do not fuse with their neighbours to form a syncytium as occurs in skeletal muscle, but remain mononucleated, branched cells connected via intercellular junctions.

Presumptive myocardial cells form a continuous sheet of cuboidal cells which line the ventral splanchnic wall of the pericardial cavity in stage 9 (unfolded) embryos. From this time, an endocardial plexus forms between the splanchnopleuric coelomic epithelium and the endoderm. The plexus cells coalesce to establish bilateral, hollow tubular structures which fuse in the midline to form a single endocardial tube. After head folding, the endocardium is separated from the myocytes of the primitive heart tube by a fine extracellular reticulum, formerly referred to as cardiac jelly, which is secreted by the myocardial cells. The extracellular matrix of the heart contains inductive signals, also secreted by the myocardial cells, which transform competent cells of the endocardial epithelium into free mesenchymal cells. Thus during cardiac development, presumptive myocardial cells engage in several processes at once: they divide and differentiate to form a functional myocardium; they secrete matrix and inductive factors that will modify the differentiation of other cells; and they participate in the bending and rotation of the primitive heart tube, and differential growth within its walls, which will ultimately produce the four-chambered adult heart.

Overt differentiation of the primitive myocardial cells begins at about the time of fusion of the endocardial tube. As the primitive heart tube is formed, the presumptive myocardial cells start to express genes that encode characteristic myocardial proteins, including myosin, actin, troponin and other components of the contractile apparatus. Myofibrils begin to appear in the developing muscle cells, and the first functional heart beats start soon afterwards.

The regulatory mechanisms underlying differentiation of cardiac muscle appear to be distinct from those of skeletal muscle. Although it is anticipated that counterparts will be found for the transcriptional factors Myf-5, myogenin, MyoD and Myf-6, which are responsible for inducing differentiation of skeletal muscle, the corresponding factors for cardiac myogenesis have yet to be identified. During fetal maturation, successive changes in gene expression give rise to the characteristics of fetal, neonatal and adult myocardium and are responsible for the divergence of the properties of atrial and ventricular
Committed cardiac myoblasts do not fuse to form multinucleated myotubes as occurs in skeletal muscle, but remain as single cells coupled physically and electrically through intercellular junctions. Moreover, differentiated cardiac muscle cells continue to divide during fetal development, and withdraw from the cell cycle only after birth. This is markedly different from skeletal muscle development, in which differentiation, including the activation of muscle-specific genes, coincides with withdrawal from the cell cycle.

Concurrent with development of the contractile proteins of cardiac muscle, cardiac muscle cells develop numerous specific heart granules which contain substances shown to induce natriuresis and diuresis, and a family of polypeptides generally known as atrial natriuretic peptides. Specific heart granules develop from the Golgi complex in both atria and ventricles during fetal life, but become restricted to atrial muscle in the adult. Atrial natriuretic peptide is measurable when the heart is recognizably four-chambered. Within the atria almost all cells are capable of its synthesis.

**Contractile protein isoforms of cardiac muscle**

As in skeletal muscle, the contractile proteins of cardiac muscle exist in a number of tissue- and stage-specific forms. The cardiac isoform of α-actin is not identical to the skeletal muscle form, and is encoded by a different gene, although the two are so similar as to be functionally interchangeable. Both skeletal and cardiac isoforms of sarcomeric actin are expressed in fetal ventricular muscle. The mRNA for skeletal α-actin increases postnatally and exceeds that of cardiac actin in the adult.

The myosin heavy chain of human cardiac muscle exists in two isoforms, α and β, both of which are present in the fetal heart. The α-form persists as the adult isoform in atrial muscle, whereas the β-form (which is associated with a slower rate of contraction) predominates in ventricular muscle. Interestingly, the β-form of myosin heavy chain in cardiac muscle is identical to the isoform in slow twitch skeletal muscle. This identity between cardiac and slow twitch skeletal protein isoforms is true of several proteins, including ventricular myosin light chains and cardiac troponin-C. Other proteins, such as troponin-I and -T, exist in cardiac-specific forms in the adult, although skeletal isoforms are expressed in the fetus and neonate. The appearance of cardiac-specific isoforms of troponin-I and -T in the blood, following their release from damaged cardiac cells, is now a standard diagnostic test for myocardial infarction.

Under some experimental conditions the contractile protein isoforms expressed by mature cardiac muscle may change in the adult mammal. Two established influences in this respect are thyroid hormone, and mechanical...
stretch induced by pressure overload. Transitions in both the heavy chains and light chains of myosin have been shown to take place in the human heart under conditions of pathological overload, but the functional significance of these changes is not clear.

**Development of the impulse-conducting tissues**

The impulse-generating and conducting system of the heart is formed from muscle cells that differ in their morphology from the working cardiac cells which make up the bulk of the myocardium. Cells of the mature conduction system retain some similarities to the myocardium of the early heart tube, and share with that embryonic tissue a distinctive pattern of expression of many genes, including those encoding contractile proteins and acetylcholinesterase. This suggests that divergence of conducting tissues and working myocardium takes place at an early embryonic stage. A cytological marker specific for the conduction system, the sulphate-3-glucuronyl carbohydrate moiety of glycoproteins, is expressed by 32 days of development and is downregulated during the later stages of cardiac septation. Its distribution strongly suggests that the conduction tissue in humans originates in a ring of specialized myocardial cells located at the interventricular foramen of the early heart.

**Lack of regeneration of cardiac muscle**

In skeletal muscle, a population of precursor cells, satellite cells, is retained in adult life, and constitutes a pool of myoblasts which is capable of dividing, fusing with existing muscle fibres, and initiating regeneration after damage. Cardiac muscle contains no equivalent of these cells, and is therefore incapable of regeneration. There is experimental evidence that temporary ischaemia injures cardiac cells in a reversible manner (Schwanger et al 1987), whereas longer periods of ischaemia produce irreversible damage.

CHAPTER 7 – Skin and its appendages

In this chapter, the types and functions of skin in different parts of the body are described first, followed by the microstructure of the epidermis and dermis, and the appendages of skin including the pilosebaceous units and the sweat glands and nails. The development of skin, natural skin lines and age-related changes, and clinical aspects of skin, e.g. grafts, surgical skin flaps and wound healing, are also described. The integumental system includes the skin and its derivatives, hairs, nails, sweat and sebaceous glands; subcutaneous fat and deep fascia; the mucocutaneous junctions around the openings of the body orifices; and the breasts. Mucocutaneous junctions and breast tissues are covered in the appropriate regional sections.

TYPES AND FUNCTIONS OF SKIN

The skin covers the entire external surface of the body, including the external auditory meatus, the lateral aspect of the tympanic membrane and the vestibule of the nose. It is continuous with the mucosae of the alimentary, respiratory and urogenital tracts at their respective orifices, where the specialized skin of mucocutaneous junctions is present. It also fuses with the conjunctiva at the margins of the eyelids, and with the lining of the lachrymal canaliculi at the lachrymal puncta. Skin forms 8% of the total body mass. Its surface area varies with height and weight, e.g. in an individual of 1.8 m and weighing 90 kg, the surface area of the skin is approximately 2.2 m$^2$. Its thickness ranges from 1.5–4.0 mm, according to its state of maturation, ageing and regional specializations.

The skin forms a self-renewing interface between the body and its environment, and is a major site of intercommunication between the two. Within limits, it forms an effective barrier against microbial invasion, and has properties which can protect against mechanical, chemical, osmotic, thermal and UV radiation damage. It is an important site of immune surveillance against the entry of pathogens and the initiation of primary immune responses. Skin carries out many biochemical synthetic processes, including the formation of vitamin D under the influence of ultraviolet B (UVB) radiation and synthesis of cytokines and growth factors. Skin is the target of a variety of hormones. These activities can affect the appearance and function of individual skin components, such as the sebaceous glands, the hairs and the pigment-producing cells.

Control of body temperature is an important function of skin, and is effected mainly by regulation of heat loss from the cutaneous circulation through the rapid increase or reduction in the flow of blood to an extensive external surface area: the process is assisted by sweating. Skin is involved in sociosexual communication and, in the case of facial skin, can signal emotional states by means of muscular and vascular responses. It is a major sense organ, richly supplied by nerve terminals and specialized receptors for touch, temperature, pain and other stimuli.

Skin has good frictional properties, assisting locomotion and manipulation by its texture. It is elastic, and can be stretched and compressed within limits. The outer surface is covered by various markings, some of them are large and conspicuous and others are microscopic, or are only revealed after manipulation or incision of the skin. These markings are often referred to collectively as skin lines.

The colour of human skin is derived from, and varies with, the amount of blood (and
its degree of oxygenation) in the cutaneous circulation, the thickness of the cornified layer, and the activity of specialized cells which produce the pigment melanin. Melanin has a protective role against ultraviolet radiation, and acts as a scavenger of harmful free radicals. Racial variations in colour are mainly due to differences in the amount, type and distribution of melanin, and are genetically determined.

The appearance of skin is affected by many other factors, e.g. size, shape and distribution of hairs and of skin glands (sweat, sebaceous and apocrine), changes associated with maturation, ageing, metabolism, pregnancy. The general state of health is reflected in the appearance and condition of the skin, and the earliest signs of many systemic disorders may be apparent in the skin. Examination of the skin, therefore, is of importance in the diagnosis of more than just skin disease.

**CLASSIFICATION OF SKIN**

Although skin in different parts of the body is fundamentally of similar structure, there are many local variations in parameters such as thickness, mechanical strength, softness, flexibility, degree of keratinization (cornification), sizes and numbers of hairs, frequency and types of glands, pigmentation, vascularity, innervation. Two major classes of skin are distinguished: they cover large areas of the body and show important differences of detailed structure and functional properties. These are thin, hairy (hirsute) skin, which covers the greater part of the body, and thick, hairless (glabrous) skin, which forms the surfaces of the palms of the hands, soles of the feet, and flexor surfaces of the digits (Fig. 7.1, Fig. 7.2, see Fig. 7.4).
Fig. 7.1 The organization of skin, comparing the structures found in thick, hairless (plantar and palmar) skin with thin, hairy (hirsute) skin. The epidermis has been partially peeled back to show the interdigitating dermal and epidermal papillae.

Fig. 7.2 The interfollicular epidermis of human thin skin. Note the thin cornified layer (C) in comparison with Fig. 7.4 (which
Fig. 7.4 The epidermis and papillary dermis (P) of human thick skin, showing the thick cornified layer (C, stratum corneum), the eosinophilic clear layer (L, stratum lucidum), the granular layer (G, stratum granulosum), the prickle cell layer (S, stratum spinosum) and the basal layer (B, stratum basale). Capillary loops (arrows) are seen entering the deep papillae (rete ridges) of the dermis, between downward-projecting epidermal rete pegs.
MICROSTRUCTURE OF SKIN AND SKIN APPENDAGES

EPIDERMIS

The epidermis (Fig. 7.2, Fig. 7.3) is a compound tissue consisting mainly of a continuously self-renewing, keratinized, stratified squamous epithelium: the principal cells are called keratinocytes. Nonkeratinocytes within the mature epidermis include melanocytes (pigment-forming cells from the embryonic neural crest), Langerhans cells (immature antigen-presenting dendritic cells derived from bone marrow), and lymphocytes. Merkel cells, which may function as sensory mechanoreceptors or possibly as part of the dispersed neuroendocrine system, are associated with nerve endings. Free sensory nerve endings are sparsely present within the epidermis. In routine histological preparations, the non-keratinocytes and Merkel cells are almost indistinguishable, and appear as clear cells surrounded by a clear space produced by shrinkage during processing. Their cytoplasm lacks prominent filament bundles.

The population of keratinocytes undergoes continuous renewal throughout life: a mitotic layer of cells at the base replaces those shed at the surface. As they move away from the base of the epidermis, keratinocytes undergo progressive changes in shape and content. They transform from polygonal living cells to non-viable flattened squames full of intermediate filament proteins (keratins) embedded in a dense matrix of cytoplasmic proteins to form mature keratin. The process is known as keratinization or, more properly, cornification.

The epidermis can be divided into a number of layers from deep to superficial as
follows: basal layer (stratum basale), spinous or prickle cell layer (stratum spinosum), granular layer (stratum granulosum), clear layer (stratum lucidum) and cornified layer (stratum corneum) (Fig. 7.4). The first three of these layers are metabolically active compartments through which cells pass and change their form as they progressively differentiate. The more superficial layers of cells undergo terminal keratinization, or cornification, which involves not only structural changes in keratinocytes, but also alterations in their relationships with each other and with non-keratinocytes, and molecular changes within the intercellular space.

The epidermal appendages (pilosebaceous units, sweat glands and nails) are formed developmentally by ingrowth of the general epidermis, and the latter is thus referred to as the interfollicular epidermis.

**Keratinocytes**

**Basal layer**

The basal or deepest layer of cells, adjacent to the dermis, is the layer where cell proliferation in the epidermis takes place. This layer contacts a basal lamina (Fig. 7.5, see Fig. 2.7), which is a thin layer of specialized extracellular matrix, not usually visible by light microscopy. By routine electron microscopy the basal lamina appears as a clear lamina lucida (adjacent to the basal cell plasma membrane) and a darker lamina densa. The basal plasma membrane of the basal keratinocytes, together with the extracellular basal lamina (lamina lucida and lamina densa) and anchoring fibrils within the subjacent dermal matrix (the lamina fibroreticularis), which insert into the lamina densa and loop around bundles of collagen, collectively form the basement membrane zone (BMZ) which constitutes the dermo-epidermal junction. This is a highly convoluted interface, particularly in thick, hairless skin, where dermal papillae (rete ridges) project superficially into the epidermal region, interlocking with adjacent downward projections of the epidermis (rete pegs) (Fig. 7.4).
The majority of basal layer cells (Fig. 7.3) are columnar to cuboidal in shape, with large (relative to their cytoplasmic volume) mainly euchromatic nuclei and prominent nucleoli. The cytoplasm contains variable numbers of melanosomes and, characteristically, keratin filament bundles corresponding to the tonofilaments of classic electron microscopy. In the basal keratinocytes these keratins are mostly K5 and K14 proteins. The plasma membranes of apposed cells are connected by desmosomes, and the basal plasma membrane is linked to the basal lamina at intervals by hemidesmosomes (Fig. 7.5, see Fig. 1.5). Melanocytes (see Fig. 7.9), occasional Langerhans cells (see Fig. 7.3) and Merkel cells (see Fig. 3.30) are interspersed among the basal keratinocytes. Merkel cells are connected to keratinocytes by desmosomes, but melanocytes and Langerhans cells lack these specialized contacts. Intraepithelial lymphocytes are present in small numbers.
At any one time the basal layer of the epidermis contains keratinocytes with different fates. These include multipotent stem cells. On division these may self-renew or produce a daughter cell which is committed to differentiate after undergoing further transit amplifying cell divisions. The activity of stem cells and transit amplifying cells in the basal layer provides a continuous supply of differentiating cells which enter the prickle cell layer. The great majority of these cells are postmitotic, although some cell division may occur in the more basal regions of the prickle cell layer. Stem cells are thought to reside mainly in the troughs of rete pegs, and in the outer root sheath bulge of the hair follicle, but they cannot easily be distinguished morphologically. The distribution of stem cells and the size of their proliferative units (see below) may be quite variable in human skin (Ghazizadeh & Taichman 2005).

The organization of the basal layer and overlying progeny cells is thought to form a series of columns. Several layers of prickle and granular cells overlie a cluster of six to eight basal cells, forming a columnar proliferative unit. Each group of basal cells consists of a central stem cell with an encircling ring of transit amplifying proliferative cells and postmitotic maturing cells. From the periphery of this unit, postmitotic cells transfer into the prickle cell layer. The normal total epidermal turnover time is between 52 and 75 days. In some pathologies of skin, turnover rates and transit times can be exceedingly rapid, e.g. in psoriasis, total epidermal turnover time may be as little as 8 days. The control of keratinocyte proliferation and differentiation is beyond the scope of this publication but is reviewed in Niemann & Watt (2002) and Byrne et al (2003).

**Prickle cell layer**

The prickle cell layer (Fig. 7.3, Fig. 7.6) consists of several layers of closely packed keratinocytes that interdigitate with each other by means of numerous cell surface projections. The cells are anchored to each other by desmosomes that provide tensile strength and cohesion to the layer. These suprabasal cells are committed to terminal differentiation and gradually move upwards towards the cornified layer as more cells are produced in the basal layer. When skin is processed for routine light microscopy, the cells tend to shrink away from each other except where they are joined by desmosomes, which gives them their characteristic spiny appearance. Prickle cell cytoplasm contains prominent bundles of keratin filaments, (mostly K1 and K10 keratin proteins) arranged concentrically around a euchromatic nucleus, and attached to the dense plaques of desmosomes. The cytoplasm also contains melanosomes, either singly or aggregated within membrane-bound organelles (compound melanosomes). Langerhans cells (see Fig. 7.11) and the occasional associated lymphocyte are the only non-keratinocytes present in the prickle cell layer.
Fig. 7.6 The superficial layers of human thick skin at high magnification, showing the deeply stained keratohyalin granule-containing cells of the granular layer (G) between the prickle cell or spinous layer (S) and the clear (or lucid, L) and cornified (C) layers above. Note that the clear layer is only translucent in unstained preparations and appears eosinophilic, as here, after staining.
Granular layer

Extensive changes in keratinocyte structure occur in the three to four layers of flattened cells in the granular layer. The nuclei become pyknotic and begin to disintegrate; organelles such as ribosomes and membrane-bound mitochondria and Golgi bodies degenerate; and keratin filament bundles become more compact and associated with irregular, densely staining keratohyalin granules (Fig. 7.6). Small round granules (100 × 300 nm) with a lamellar internal structure (lamellar granules, Odland bodies, keratinosomes) also appear in the cytoplasm. Keratohyalin granules contain a histidine-rich, sulphur-poor protein (profilaggrin) which, when the cell reaches the cornified layer, becomes modified to filaggrin. The lamellar granules are concentrated deep to the plasma membrane, with which they fuse, releasing their hydrophobic glycoprophospholipid contents into the intercellular space within the layer.
and also between it and the cornified layer. They form an important component of the permeability barrier of the epidermis, rendering it relatively waterproof.

**Clear layer**

The clear layer is only found in thick palmar or plantar skin. It represents a poorly understood stage in keratinocyte differentiation. It stains more strongly than the cornified layer with acidic dyes (Fig. 7.6), is more refractile optically, and often contains nuclear debris. Ultrastructurally, its cells contain compacted keratin filaments and resemble the incompletely keratinized cells which are occasionally seen in the innermost part of the cornified layer of thin skin.

**Cornified layer**

The cornified layer (Fig. 7.3, Fig. 7.6) is the final product of epidermal differentiation, or cornification. It consists of closely packed layers of flattened polyhedral squames (Fig. 7.7), ranging in surface area from 800 to 1100 µm². These cells overlap at their lateral margins and interlock with cells of apposed layers by ridges, grooves and microvilli. In thin skin this layer may be only a few cells deep, but in thick skin it may be more than 50 cells deep. The plasma membrane of the squame appears thicker than that of other keratinocytes, partly due to the cross-linking of a soluble precursor, involucrin, at the cytoplasmic face of the plasma membrane, in the complex insoluble cornified envelope. The outer surface is also covered by a monolayer of bound lipid. The intercellular region contains extensive lamellar sheets of glycolipid derived from the lamellar granules of the granular layer. The cells lack a nucleus and membranous organelles, and consist solely of a dense array of keratin filaments embedded in a cytoplasmic matrix which is partly composed of filaggrin derived from keratohyalin granules.
Under normal conditions the production of epidermal keratinocytes in the basal layer is matched by loss of cells from the cornified layer. Desquamation of these outer cells is normally imperceptible. When excessive, it appears in hairy regions as dandruff, and more extensively in certain diseases and, to a lesser extent, after sunburn, as peeling, scaling and exfoliation. The thickness of the cornified layer can be influenced by local environmental factors, particularly abrasion, which can lead to a considerable thickening of the whole epidermis including the cornified layer. The soles of the feet become much thickened if an individual habitually walks barefoot, and cornified pads develop in areas of frequent pressure, e.g. corns from tight shoes, palmar calluses in manual workers, and digital calluses in guitar players.

**Keratins**

Epidermal keratinization has historically been the term applied to the final stages of keratinocyte differentiation and maturation, during which cells are converted into tough cornified squames. However, this is now regarded as ambiguous because the term keratin is assumed to refer to the protein of epithelial intermediate filaments, rather than (as previously) to the whole complement of proteins in the terminally differentiated cell of the stratum corneum.
Keratins are the intermediate filament proteins found in all epithelial cells. There are two types, type I (acidic) and type II (neutral/basic); they form heteropolymers, are coexpressed in specific pairs and are assembled into 10 nm intermediate filaments. Fifty-four different keratin genes have been recognized and their protein products are numbered. The nomenclature for human keratins and keratin genes has recently been revised and is given in Schweizer et al (2006). Different keratin pairs are expressed according to epithelial cell differentiation; antibodies to individual keratins are useful analytical tools (Fig. 7.8). Keratins K5 and K14 are expressed by basal keratinocytes. New keratins, K1 and K10, are synthesized suprabasally. In the granular layer the filaments become associated with keratohyalin granules containing profilaggrin, a histidine-rich phosphorylated protein. As the cells pass into the cornified layer, profilaggrin is cleaved by phosphatases into filaggrin which causes aggregation of the filaments and forms the matrix in which they are embedded. Other types of keratin expression occur elsewhere, particularly in hair and nails, where highly specialized hard, or trichocyte, keratin is expressed. This becomes chemically modified and is much tougher than in the general epidermis. For a recent review of keratin function see Gu & Coulombe 2007.
Epidermal lipids

The epidermis serves as an important barrier to the loss of water and other substances through the body surface (apart from in sweating and sebaceous secretion). A variety of lipids are present and synthesized in the epidermis, including triglycerides and fatty acids, phospholipids, cholesterol, cholesterol esters, glycosphingolipids and ceramides. An intermediate in the synthesis of cholesterol, 7-dehydrocholesterol, is the precursor of vitamin D, which is also synthesized in the skin. The content and composition of epidermal lipids change with differentiation. Phospholipids and glycolipids at first accumulate within keratinocytes above the basal layer, but higher up they are broken down and are practically absent from the cornified
layer. Cholesterol and its esters, fatty acids and ceramides accumulate towards the surface, and are abundant in the cornified layer. The lamellar arrangement of the extracellular lipids is a major factor in their barrier function.

**Melanocytes**

Melanocytes are melanin pigment-forming cells derived from the neural crest (Fig. 7.9, Fig. 7.10). They are present in the epidermis and its appendages, in oral epithelium, some mucous membranes, the uveal tract (choroid coat) of the eyeball, parts of the middle and internal ear and in the pial and arachnoid meninges at the base of the brain. The cells of the retinal pigment epithelium, developed from the outer wall of the optic cup, also produce melanin, and neurones in different locations within the brainstem (e.g. the locus coeruleus and substantia nigra) synthesize a variety of melanin called neuromelanin. True melanins are high molecular weight heteropolymers attached to structural protein. In humans there are two classes, the brown-black eumelanin, and the red-yellow phaeomelanin, both derived from the substrate tyrosine. Most natural melanins are mixtures of eumelanin and phaeomelanin, and phaeomelanic pigments, trichochromes, occur in red hair.
Melanocytes are dendritic cells, and lack desmosomal contacts with apposed keratinocytes, though hemidesmosomal contacts with the basal lamina are present. In routine tissue preparations, melanocytes appear as clear cells in the basal layer of the epidermis; numbers per unit area of epidermis range from 2300 per mm$^2$ in cheek skin to 800 per mm$^2$ in abdominal skin. It is estimated that a single melanocyte may be in functional contact via its dendritic processes with up to 30 keratinocytes. The nucleus is large, round, and euchromatic, and the cytoplasm contains intermediate filaments, a prominent Golgi complex and vesicles and associated rough endoplasmic reticulum, mitochondria, and coated vesicles, together with a characteristic organelle, the melanosome.

The melanosome is a membrane-bound structure which undergoes a sequence of developmental stages during which melanin is synthesized and deposited within it by a tyrosine–tyrosinase reaction. Mature melanosomes move into the dendrites along the surfaces of microtubules and are transferred to keratinocytes through their phagocytic activity. Keratinocytes engulf and internalize the tip of the dendrite with the subsequent pinching off of melanosomes into the keratinocyte cytoplasm. Here, they may exist as individual granules in heavily pigmented skin, or be packaged within secondary lysosomes as melanosome complexes in lightly pigmented skin. In basal keratinocytes they can be seen to accumulate in a crescent-shaped cap over the distal part of the nucleus. As the keratinocytes progress towards the surface of the epidermis, melanosomes undergo degradation, and melanin remnants in the cornified layer form dust-like particles. Melanosomes are degraded more rapidly in Caucasian skin than in dark-skinned races, where melanosomes persist in cells of the more superficial layers.

Melanin has biophysical and biochemical properties related to its functions in skin. It protects against the damaging effects of UV radiation on DNA and is also an efficient scavenger of damaging free radicals. However a high concentration of melanin may adversely affect synthesis of vitamin D in darker-skinned individuals living in northern latitudes. Melanin pigmentation is both constitutive and facultative. Constitutive pigmentation is the intrinsic level of pigmentation and is genetically determined, whereas facultative pigmentation represents reversible changes induced by
environmental agents, e.g. UV and X-radiation, chemicals, and hormones. Racial variations in pigmentation are due to differences in melanocyte morphology and activity rather than to differences in frequency or distribution. In naturally heavily pigmented skins the cells tend to be larger, more dendritic, and to contain more large, late-stage melanosomes than melanocytes of paler skins. The keratinocytes in turn contain more melanosomes, individually dispersed, whereas in light skins, the majority are contained within secondary lysosomes to form melanosome complexes.

Response to UV light includes immediate tanning, pigment darkening, which can occur within a matter of minutes, probably due to photo-oxidation of pre-existing melanin. Delayed tanning occurs after about 48 hours, and involves stimulation of melanogenesis within the melanocytes, and transfer of additional melanosomes to keratinocytes. There may also be some increase in size of active melanocytes, and in their apparent numbers, mainly through activation of dormant cells. Freckles in the skin of red-haired individuals are usually thought to be induced by UV, though they do not appear until several years after birth, despite exposure. Paradoxically, melanocytes are significantly fewer in freckles than in adjacent paler epidermis, but they are larger and more active. What determines the onset of freckles, or their individual location, is not known.

Adrenocorticotrophin (ACTH) is thought to affect melanocyte activity, and is probably responsible for the hyperpigmentation associated with pituitary and adrenal disorders. In pregnancy, higher levels of circulating oestrogens and progesterone are responsible for the increased melanization of the face, abdominal and genital skin, and the nipple and areola, much of which may remain permanently.

In albinism, the tyrosinase required for melanin synthesis is either absent or inactive, and melanocytes, though present, are relatively quiescent cells in an otherwise normal epidermis. Melanocytes decrease significantly in numbers in old age, and are absent from grey-white hair. For further reading on melanocyte function in health and disease, see Goding (2007).

Langerhans cells

Langerhans cells (Fig. 7.11) are immature dendritic antigen-presenting cells (see p. 79) regularly distributed throughout the basal and prickle cell layers of the epidermis and its appendages, apart from the sweat gland. They are also present in other stratified squamous epithelia, including the buccal, tonsillar and oesophageal epithelia, as well as the cervical and vaginal mucosae and the transitional epithelium of the bladder. They are found in the conjunctiva, but not in the cornea. In routine preparations they appear as clear cells, relatively high in the stratified layer. They enter the epidermis from the bone marrow during development to establish the postnatal population (460–1000/mm², 2–3% of all epidermal cells, with regional variations), and this is maintained by continual replacement from the marrow.

The nucleus is euchromatic and markedly indented and the cytoplasm contains a well-developed Golgi complex, lysosomes (which often contain ingested melanosomes), and a characteristic organelle, the Birbeck granule. The latter are discoid, cup-shaped, or have a distended vesicle resembling the head of a tennis racket; in section they often appear as a cross-striated rod 0.5 µm long and 30 nm wide. When stimulated by antigen, Langerhans cells migrate out of the epidermis to lymphoid
tissues (see Fig. 4.14). Their numbers are increased in chronic skin inflammatory disorders, particularly of an immune aetiology, such as some forms of dermatitis.

**Merkel cells**

Merkel cells are present as clear oval cells, singly or in groups, in the basal layer of the epidermis, especially of thick skin. They are also present in the outer root sheath of some large hair follicles. Merkel cells are derived embryologically from the neural crest and are not related developmentally to keratinocytes, as was once thought. They can be distinguished histologically from other clear cells (melanocytes and Langerhans cells) only by immunohistochemical and ultrastructural criteria.

Short, stiff processes of their plasma membrane interdigitate with adjacent basal keratinocytes, to which the Merkel cell is attached by small desmosomes. The cytoplasm contains numerous closely-packed intermediate filaments (simple epithelial keratins, mostly K8 and K18 but also K19 and K20), and characteristic 80–110 µm dense-core granules. The basal plasma membrane is closely apposed to the membrane of an axonal terminal. Merkel cells are thought to function as neuroendocrine sensory receptors, and are slowly adapting mechanoreceptors which respond to directional deformations of the epidermis and direction of hair movement by releasing a transmitter from their dense-core cytoplasmic granules.
DERMIS

The dermis (Fig. 7.1, Fig. 7.4, see Fig. 7.17) is an irregular, moderately dense connective tissue. It has a matrix composed of an interwoven collagenous and elastic network in an amorphous ground substance of glycosaminoglycans, glycoproteins and bound water, which accommodates nerves, blood vessels, lymphatics, epidermal appendages and a changing population of cells. Mechanically, the dermis provides considerable strength to the skin by virtue of the number and arrangement of its collagen fibres (which give it tensile strength), and its elastic fibres (which give it elastic recoil). The density of its fibre meshwork, and therefore its physical properties, varies within an area, in different parts of the body, and with age and sex. The dermis is vital for the survival of the epidermis, and important morphogenetic signals are exchanged at the interface between the two both during development and postnatally. The dermis can be divided into two zones, a narrow superficial papillary layer and a deeper reticular layer: the boundary between them is indistinct.
Adult dermal collagen is mainly of types I and III, in proportions of 80–85% and 15–20% respectively. The coarser-fibred type I is predominant in the deeper, reticular dermis, and the finer type III is found in the papillary dermis and around blood vessels. Type IV collagen is found in the basal lamina between epidermis and dermis, around Schwann cells of peripheral nerves and endothelial cells of vessels. Types V, VI and VII are minor collagenous
components of the dermis. Elastic fibres form a fibrous network interwoven between the collagen bundles throughout the dermis, and are more prominent in some regions, e.g. the axilla.

Two major categories of cell are present in postnatal dermis, permanent and migrant, as is typical of all general connective tissues (see Ch. 2). The permanent resident cells include cells of organized structures such as nerves, vessels and cells of the arrector pili muscles, and the fibroblasts, which synthesize all components of the dermal extracellular matrix. The migrant cells originate in the bone marrow (Fig. 4.12) and include macrophages, mast cells, eosinophils, neutrophils, T and B cells (including antibody-secreting plasma cells), and dermal interstitial dendritic cells which are capable of immune surveillance and antigen presentation.

**Layers of the dermis**

**Papillary layer**

The papillary layer is immediately deep to the epidermis (Fig. 7.4), and is specialized to provide mechanical anchorage, metabolic support, and trophic maintenance to the overlying epidermis, as well as supplying sensory nerve endings and blood vessels. The cytoskeleton of basal epidermal keratinocytes is linked to the fibrous matrix of the papillary dermis through the attachment of keratin filament bundles to hemidesmosomes, then via anchoring filaments of the basal lamina, to the anchoring fibrils of type VII collagen which extend deep into the papillary dermis (Fig. 7.5). This arrangement provides a mechanically stable substratum for the epidermis.

The superficial surface of the dermis is shaped into numerous papillae or rete ridges, which interdigitate with rete pegs in the base of the epidermis and form the dermo-epidermal junction at their interface. The papillae have round or blunt apices which may be divided into several cusps. In thin skin, especially in regions with little mechanical stress and minimal sensitivity, papillae are few and very small, while in the thick skin of the palm and sole of the foot they are much larger, closely aggregated, and arranged in curved parallel lines following the pattern of ridges and grooves on these surfaces (Fig. 7.1). Lying under each epidermal surface ridge are two longitudinal rows of papillae, one on either side of the epidermal rete pegs through which the sweat ducts pass on the way to the surface. Each papilla contains densely interwoven, fine bundles of types I and III collagen fibres and some elastic fibrils. Also present is a capillary loop (Fig. 7.4), and in some sites, especially in thick hairless skin, Meissner's corpuscle nerve endings.

**Reticular layer**

The reticular layer merges with the deep aspect of the papillary layer. Its
bundles of collagen fibres are thicker than those in the papillary layer and interlace with them and with each other to form a strong but deformable three-dimensional lattice, in which many fibres are parallel to each other, and which contain a variable number of elastic fibres. The predominant orientation of the collagen fibres may be related to the local mechanical forces on the dermis and thus may be involved in the development of skin lines.

Hypodermis

Also known as the superficial fascia, the hypodermis is a layer of loose connective tissue of variable thickness which merges with the deep aspect of the dermis. It is often adipose, particularly between the dermis and musculature of the body wall. It mediates the increased mobility of the skin, and the adipose component contributes to thermal insulation, acts as a shock absorber and constitutes a store of metabolic energy. Subcutaneous nerves, vessels and lymphatics travel in the hypodermis, their main trunks lying in its deepest part, where adipose tissue is scant. In the head and neck, the hypodermis also contains muscles, such as platysma, which are remnants of more extensive sheets of skin-associated musculature found in other mammals.

The quantity and distribution of subcutaneous fat differs in the sexes. It is generally more abundant and widely distributed in females. In males it diminishes from the trunk to the extremities, and this distribution is more obvious in middle age, when the total amount increases in both sexes. The amount of adipose tissue in the hypodermis, as elsewhere, reflects the quantity of lipid stored in its adipocytes rather than a change in the number of cells. There is an association with climate (rather than race), and superficial fat is more abundant in colder geographical regions. The hypodermis is most distinct on the lower anterior abdominal wall, where it contains much elastic tissue and appears many-layered as it passes through the inguinal regions into the thighs. It is similar in the limbs and the perineum, but is thin where it passes over the dorsal aspects of the hands and feet, the sides of the neck and face, around the anus, and over the penis and scrotum. It is almost absent from the external ears but is particularly dense in the scalp, palms and soles, where it is crossed by numerous strong connective tissue bands binding the hypodermis and skin to underlying structures: these are part of the deep fascia, but are known regionally as aponeuroses of the scalp, palm and sole.
PILOSEBACEOUS UNIT

The pilosebaceous unit consists of the hair and its follicle with an associated arrector pili muscle, sebaceous gland, and sometimes an apocrine gland (Fig. 7.1, Fig. 7.12). Not all elements of the unit occur together in all body regions.

Fig. 7.12 A pilosebaceous unit in thin, hairy skin seen at low magnification. The hair follicle, hair shaft and hair root extend almost vertically through the field, the follicle joining the interfollicular epidermis (top). To the left of the follicle are the acini of a sebaceous gland, which is also sectioned tangentially through its capsule (centre bottom, below the portion of the hair follicle in section); the gland opens into the follicle in centre field. The associated arrector pili smooth muscle (thin red fibre bundle) is seen to the left of the sebaceous gland, following its contours.

Hairs

Hairs are filamentous cornified structures present over almost the entire body surface.
They grow out of the skin at a slant (Fig. 42.1) as is evident in the sloping of the hairs on the dorsum of forearm, hand and fingers towards the ulnar side. Hairs are absent from several areas of the body, including the thick skin of the palms, soles, the flexor surfaces of the digits, the thin skin of the umbilicus, nipples, glans penis and clitoris, the labia minora and the inner aspects of the labia majora and prepuce. The presence, distribution and relative abundance of hair in certain regions such as the face (in males), pubis and axillae, are secondary sexual characteristics which play subtle roles in sociosexual communication. There are racial variations in density, form, distribution and pigmentation, as well as individual variations. Hairs assist minimally in thermoregulation: on the scalp they provide some protection against injury and the harmful effects of solar radiation. They have a sensory function.

Hairs vary from approximately 600 per cm$^2$ on the face to 60 per cm$^2$ on the rest of the body. In length they range from less than a millimetre to more than a metre, and in width from 0.005 to 0.6 mm. They vary in form, being straight, coiled, helical or wavy, and differ in colour depending on the type and degree of pigmentation. Curly hairs tend to have a flattened cross-section, and are weaker than straight hairs. In general, body hairs are longest and coarsest in Caucasians and least noticeable in Mongolian races. Over most of the body surface hairs are short and narrow (vellus hairs) and in some areas these hairs do not project beyond their follicles, e.g. in eyelid skin. In other regions they are longer, thicker and often heavily pigmented (terminal hairs); these include the hairs of the scalp, the eyelashes and eyebrows and the postpubertal skin of the axillae and pubis, and the moustache, beard and chest hairs of males. The presence in females of coarse terminal hairs in a male-like pattern is termed hirsutism and is usually a sign of an endocrine disorder and excess androgen production (Azziz 2003).

**Hair follicle**

The hair follicle (Fig. 7.1, Fig. 7.12, Fig. 7.13A) is a downgrowth of the epidermis containing a hair, which may extend deeply (3 mm) into the hypodermis, or may be more superficial (1 mm) within the dermis. Typically, the long axis of the follicle is oblique to the skin surface; with curly hairs it is also curved. There are cycles of hair growth and loss, during which the follicle presents different appearances. In the anagen phase the hair is actively growing and the follicle is at its maximum extent of development. In the involuting or catagen phase, hair growth ceases and the follicle shrinks. During the resting or telogen phase the inferior segment of the follicle is absent. This is succeeded by the next anagen phase. Further details of the hair growth cycle are given below, after the description of the anagen follicle and hair.
Fig. 7.13  A. The major structural features of the base of a hair follicle, showing the organization of the major layers of the hair and surrounding sheath, arising from the hair bulb. A dermal hair papilla invaginates the bulb, and along the basal layer of the epidermis, at its interface with the dermis, melanocytes insert their dendrites among the keratinocytes forming the hair. B. The hair bulb at the base of the human hair follicle. The dermal hair papilla invaginates the bulb from its fibrous outer sheath, carrying a loop of capillaries. Melanocytes in the germinal matrix (equivalent to the basal layer of interfollicular epidermis) extend dendrites into the adjacent layers of keratinocytes, to which they pass melanosomes. The layers of the hair shaft and root sheaths are also indicated.

Anagen follicle

The anagen follicle has several regions. The deepest is the inferior segment which includes the hair bulb region extending up to the level of attachment of the arrector pili muscle at the follicular bulge. Between this point and the site of entry of the sebaceous duct is the isthmus, above which is the infundibulum, or dermal pilary canal, which is continuous with the intraepidermal pilary canal. Below the sebaceous duct, the hair shaft and follicular wall are intimately connected, and it is only towards the upper end of the isthmus that the hair becomes free in the pilary canal. Below the infundibulum the follicle is surrounded by a thick perifollicular dermal coat containing type III collagen, elastin, sensory nerve fibres and blood vessels, and into which the arrector pili muscle fibres blend. A thick, specialized basal lamina, the glassy membrane, marks the interface between dermis and the epithelium of large hair follicles.

Hair bulb

The hair bulb forms the lowermost portion of the follicular epithelium and encloses the dermal hair papilla of connective tissue cells (Fig. 7.13B). The dermal hair papilla is an important cluster of inductive mesenchymal cells which is required for hair follicle growth in each cycle throughout adult life: it is a continuation of the layer of adventitious mesenchyme that follows the contours of the hair follicle. The hair bulb generates the hair and its inner root sheath. A hypothetical line drawn across the widest part of the hair bulb divides it into a lower germinal matrix and an upper bulb. The germinal matrix is formed of closely packed, mitotically active pluripotential keratinocytes, among which are interspersed melanocytes, and some Langerhans cells. The upper bulb consists of cells arising from the matrix. These migrate apically and differentiate along several lines. Those arising centrally form the hair medulla. Radially, successive concentric rings of cells give rise to the cortex and cuticle of the hair and outside this, to the three layers of the inner root sheath. The latter are, from within out, the cuticle of the inner root sheath, Huxley's layer and Henle's layer. Henle's layer is surrounded by the outer root sheath, which forms the cellular wall of
the follicle (Fig. 7.13). Differentiation of cells in the various layers of the hair and its inner root sheath begins at the level of the upper bulb and is asynchronous, beginning earliest in Henle's layer and Huxley's layer.

**Structure of hair and its sheaths**

A fully developed hair shaft consists of three concentric zones which are, from outwards in, the cuticle, cortex and medulla. Each has different types of keratin filament proteins and different patterns of cornification. In finer hairs the medulla is usually absent. The cuticle forms the hair surface and consists of several layers of overlapping cornified squames directed apically and slightly outwards (Fig. 7.14). Immature cuticle cells have dense amorphous granules aligned predominantly along the outer plasma membrane with a few filaments. The cortex forms the greater part of the hair shaft and consists of numerous closely packed, elongated squames which may contain nuclear remnants and melanosomes. Immature cortical cells contain bundles of closely packed filaments but no dense granules, and when fully cornified, they have a characteristic thumb-print appearance with filaments arranged in whorls. The medulla, when present, is composed of loosely aggregated and often discontinuous columns of partially disintegrated cells containing vacuoles, scattered filaments, granular material and melanosomes. Air cavities lie between the cells or even within them.
Henle’s layer and Huxley’s layer of the inner root sheath contain irregular dense keratohyalin granules and associated filaments in the precornified state. At the level of the upper bulb, Henle’s layer begins to cornify, as does Huxley’s layer at the middle of the inferior follicle. When fully differentiated, cells of both layers have a thickened cornified envelope enclosing keratin filaments embedded in a matrix. The cells of the inner root sheath cuticle undergo terminal differentiation at a level closer to the hair bulb than that of Huxley’s layer, but lack a clear-cut filament pattern such as is seen in the cortical cells of the hair shaft. As they cornify, the cuticle cells of the inner root sheath and hair become interlocked. At about the level of entry of the sebaceous duct, above the isthmus, the inner root sheath undergoes fragmentation, and the hair then lies free in the pilary canal.

The outer root sheath, beginning at the level of the upper bulb, is a single or double layer of undifferentiated cells containing glycogen. Higher up the follicle it becomes multilayered. At the isthmus all remaining cell layers of the follicle sheath become flattened, compressed and attenuated. On emerging from the isthmus, the outer root sheath assumes the stratified, differentiating characteristics of interfollicular epidermis, with which it becomes continuous. At the level of entry of the sebaceous duct, it forms the wall of the pilary canal.

Hair cycle and growth of hair

Recurrent cyclic activity of hair follicles involves growth, rest, and shedding of hair in phases. In humans, these occur in irregular cycles of variable duration: there are regional and other variations in the length of the individual phases. In the growing or anagen phase, follicle and hair are as described above. Melanocytes are active only in mid-anagen, and are capable of producing both phaeo- and eumelanosomes, which they pass to precortical and medullary keratinocytes. Changes in hair colour of an individual, usually in adolescence, are due to alterations in the dominant type of melanosome produced.

Anagen is followed by the involuting or catagen phase during which mitotic activity of the germinal matrix ceases, the base of the hair condenses into a club which moves upwards to the level of the arrector pili muscle, and the whole inferior segment of the follicle degenerates. The dermal papilla also ascends and remains close to the base of the shortened follicle and its enclosed club hair, a situation which persists during the resting or telogen phase. During telogen, melanocytes become amelanotic and can be identified only ultrastructurally. At the beginning of the next anagen, the epithelial cells at the base of the follicle divide to form a secondary hair rudiment which envelops the dermal papilla to form a new hair bulb. This grows downwards,
reforming the inferior segment of the follicle, from which a new hair grows up alongside the club hair, which is eventually shed.

Postnatally, hairs exhibit regional asynchrony of cycle duration and phase leading to an irregular pattern of growth and replacement. In some regions, such as the scalp, the cycle is measured in years; in others, such as general body hair, the cycle is much shorter and hairs are therefore limited in length. At puberty, hair growth and generation of much thicker hairs occurs on the pubes and axillae in both sexes, and on the face and trunk in males. The actions of hormones on hair growth are complex, and involve not only sex hormones, but also those of the thyroid, suprarenal cortex and pituitary glands. Androgens stimulate facial and general body hair formation. After about the first 30 years, they tend to cause the thick terminal hairs of the scalp to change to small vellus hairs, which produces recession from the forehead and sometimes almost complete male pattern baldness. In females, oestrogens tend to maintain vellus hairs: postmenopausal reduction of oestrogens may permit stronger facial and bodily hair growth. In mid-pregnancy, hair growth may be particularly active but later, often post-partum, an unusually large number of hairs enter the telogen phase and are shed before the growth cycle recommences. In older men, growth of hairs on the eyebrows and within the nostrils and external ear canals increases, whereas elsewhere on the body, growth slows and the hairs become much finer.

Measurements of the rate of growth of individual hairs vary considerably, probably because of the influence of the factors mentioned above. A rate of 0.2–0.44 mm per 24 hours in males is usually given: the higher rate occurs on the scalp. Contrary to popular myth, shaving does not appear to affect the growth rate and hair ceases growth after death.

**Sebaceous glands**

Sebaceous glands are small saccular structures (Fig. 7.1, Fig. 7.12, Fig. 7.15) lying in the dermis; together with the hair follicle and arrector pili muscle, they constitute the pilosebaceous unit. They are present over the whole body except the thick hairless skin of the palm, soles and flexor surfaces of digits. Typically, they consist of a cluster of secretory acini which open by a short common duct into the dermal pilary canal of the hair follicle. They release their lipid secretory product, sebum, into the canal by a holocrine mechanism (see Ch. 2). In some areas of thin skin which lack hair follicles, their ducts open instead directly on to the skin surface, e.g. on the lips and corners of the mouth, the buccal mucosa, nipples, female breast areolae, penis, inner surface of the prepuce, clitoris and labia minora. At the margins of the eyelids, the large complex palpebral tarsal glands (Meibomian glands) are of this type. They are also present in the external auditory meatus.
In general, numbers of sebaceous glands in any given area reflect the distribution of hair follicles, ranging from an average of 100/cm² over most of the body to as many as 400–900/cm² on the face and scalp. They are also numerous in the midline of the back. Individual sebaceous glands are particularly large on the face, around the external auditory meatus, chest and shoulders, and on the anogenital surfaces. Those on the face are often related to very small vellus hairs whose follicles have particularly wide apertures.

Microscopically, the glandular acini are enclosed in a basal lamina supported by a thin dermal capsule and a rich capillary network. Each acinus is lined by a single layer of small, flat, polygonal epithelial cells (sebocytes) which ultrastructurally resemble...
undifferentiated basal keratinocytes of interfollicular epidermis. They possess euchromatic nuclei and large nucleoli, scattered keratin filaments, free ribosomes, smooth endoplasmic reticulum and rounded mitochondria, and are attached to each other by desmosomes. Functionally, they are mitotically active stem cells whose progeny move gradually towards the centre of the acinus, increasing in volume and accumulating increasingly large lipid vacuoles. The nuclei become pyknotic as the cells mature. The huge distended cells ultimately disintegrate, filling the central cavity and its duct with a mass of fatty cellular debris (Fig. 7.15). The process takes 2–3 weeks. The secretory products pass through a wide duct lined with keratinized stratified squamous epithelium into the infundibulum of the hair follicle and then to the surface of the hair and the general epidermis.

The normal functions of sebum are the provision of a protective coating on hairs, possibly helping to waterproof the epidermis, discouragement of ectoparasites and contribution to a characteristic body odour. When first formed, sebum is a complex mixture of over 50% di- and triglycerides, with smaller proportions of wax esters, squalene, cholesterol esters, cholesterol and free fatty acids. At birth, sebaceous glands are quite large, regressing later until stimulated again at puberty. At that time, sebaceous gland growth and secretory activity increase greatly in both males and females, under the influence of androgens (testicular and suprarenal), which act directly on the gland. Excessive amounts of sebum may become impacted within the duct, and this, associated with hyperkeratinization, may lead to blockage and formation of a comedone. This may become infected and inflamed, and is the primary lesion of acne. Oestrogens have an effect opposite to that of androgens, and sebum secretion is considerably lower in women, becoming greatly decreased after the age of 50 years.

**Apocrine glands**

Apocrine glands are particularly large glands of the dermis or hypodermis, classed as a type of sweat gland. Since they develop as outgrowths of the hair follicle and discharge secretion into the hair canal, they are considered here. In the adult, they are present in the axillae, perianal region, areolae, periumbilical skin, prepuce, scrotum, mons pubis and labia minora. Ceruminous glands of the external auditory meatus and the ciliary glands of the palpebral margins (Moll's glands) are also usually included in this category, but their secretions are quite different and they should be considered as distinct, specialized subtypes.

An apocrine gland consists of a basal secretory coil and a straight duct which opens into either the pilary canal above the duct of the sebaceous gland, or directly onto the skin surface if there is no associated hair. The secretory region may be as much as 2 mm wide and its coils often anastomose to form a labyrinthine network. Each coil is lined by cuboidal secretory cells whose apical cytoplasm projects into the lumen and basally is in contact with a layer of myoepithelial cells within a thick basal lamina. The secretory cells contain vacuoles, vesicles and dense granules of varying size and internal structure: the numbers and character vary with the cycle of synthesis and discharge. The mechanism of secretion is still not clear, but may involve merocrine secretion of granules, apocrine secretion or complete holocrine disintegration of the cells (see Fig. 2.5).

Apocrine activity is minimal before puberty, after which it is androgen dependent and
responsive to emotional stimuli. It is controlled by adrenergic nerves, and is sensitive to adrenaline (epinephrine) and noradrenaline (norepinephrine). The secretion is initially sterile and odourless, but it undergoes bacterial decomposition to generate potent odorous, musky compounds, including short-chain fatty acids, and steroids such as 5α-androstenone. In many animals these are potent pheromonal signals but their role in humans is less certain. Obstruction of apocrine sweat ducts and associated upper hair follicles in the axillae, breast areolae and pubic region, mainly in women, is thought to underlie Fox–Fordyce disease.

**Arrector pili muscles**

The arrector pili muscles are small bundles of closely packed smooth muscle cells which form oblique links between the dermal sheaths of hair follicles and the papillary layer of the dermis (Fig. 7.1, Fig. 7.12). They show the typical features of smooth muscle cells and are separated by narrow spaces containing collagen fibres and unmyelinated noradrenergic sympathetic axons.

The muscles are attached to the bulge region of the follicles by elastin fibrils, and are directed obliquely and towards the side to which the hair slopes superficially. The sebaceous gland occupies the angle between the muscle and the hair follicle, and muscle contraction helps to expel the gland contents. Contraction tends to pull the hair into a more vertical position and to elevate the epidermis surrounding it into a small hillock (goose bump), dimpling the skin surface where the muscle is inserted superficially. Arrector pili muscles are absent from facial, axillary, and pubic hairs, from eyelashes and eyebrows, and from the hairs around the nostrils and the external auditory meatuses.
SWEAT GLANDS

The vast majority of sweat glands (Fig. 7.16) are often classified as eccrine, although their mode of secretion includes typical merocrine mechanisms (see Ch. 2). They are long unbranched tubular structures, each with a highly coiled, secretory portion up to 0.4 mm in diameter, situated deep in the dermis or hypodermis. From there, a narrower, straight or slightly helical ductal portion emerges (Fig. 7.1). The walls of the duct fuse with the base of epidermal rete pegs and the lumen passes between the keratinocytes, often in a tight spiral, particularly in thick hairless skin (Fig. 7.17), and opens via a rounded aperture (pore) onto the skin surface (Fig. 7.7). In thick hairless skin, sweat glands discharge along the centres of friction ridges, incidentally providing fingerprint patterns for forensic analysis. Sweat glands have an important thermoregulatory function, they contribute significantly to excretion and their secretion enhances grip and sensitivity of the palms and soles.
Sweat glands are absent from the tympanic membrane, margins of the lips, nail bed, nipple, inner preputial surface, labia minora, penis and clitoris, where apocrine glands are located. Elsewhere they are numerous, their frequency ranging from 80 to over 600/cm², depending on position and genetic variation. The total number lies between 1.6 and 4.5 million, and is greatest on the plantar skin of the feet. There are many sweat glands on the
face and flexor aspects of the hands, and fewest on the surfaces of the limbs. Racial groups indigenous to warmer climates tend to have more sweat glands than those indigenous to cooler regions.

Microscopically the secretory coil consists of a pseudostratified epithelium enclosing a lumen. Three types of cell have been described: clear cells from which most of the secretion derives, dark cells which share the same lumen, and myoepithelial cells. Clear cells are approximately pyramidal in shape, and their bases rest on the basal lamina or contact myoepithelial cells. Their apical plasma membranes line lateral intercellular canaliculi which connect with the main lumen. The basolateral plasma membranes are highly folded, interdigitating with apposed clear cells, and they have the basal membrane infoldings typical of cells involved in fluid and ion transport. Their cytoplasm contains glycogen granules, mitochondria, rough endoplasmic reticulum and a small Golgi complex, but few other organelles. The nucleus is round and moderately euchromatic. Dark cells are pyramidal, and lie closer to the lumen such that their broad ends form its lining. Their cytoplasm contains a well-developed Golgi complex, numerous vacuoles and vesicles and dense glycoprotein granules which they secrete by a typical merocrine mechanism. Myoepithelial cells resemble those associated with secretory acini of the salivary glands and breast, and contain abundant myofilaments.

The intradermal sweat duct is formed of an outer basal layer and an inner layer of luminal cells connected by numerous desmosomes. The intraepidermal sweat duct (acrosyringium) is coiled, and consists of two layers of cells which, developmentally, are different from the surrounding keratinocytes and can be distinguished from them by the presence of keratin K19. The outer cells near the surface contain keratohyalin granules and lamellar granules, and undergo typical cornification. The inner cells, from a midepidermal level, contain numerous vesicles, undergo an incomplete form of cornification, and are largely shed into the lumen at the level of the cornified epidermal layer.

Sweat is a clear, odourless fluid, hypotonic to tissue fluid, and contains mainly sodium and chloride ions, but also potassium, bicarbonate, calcium, urea, lactate, amino acids, immunoglobulins and other proteins. Excessive sweating can lead to salt depletion. Heavy metals and various organic compounds are eliminated in sweat, the greater part of which is thought to be produced by the clear cells. When first secreted, the fluid is similar in composition to interstitial fluid. It is modified as it passes along the duct by the action mainly of the basal cells, which resorb sodium and chloride and some water. The hormone aldosterone enhances this activity. The sweat glands are capable of producing up to 10 litres of sweat per day, in response to thermal, emotional and taste stimuli, mediated by unmyelinated sympathetic cholinergic fibres; the glands also respond to adrenaline. Thermoregulation involves a heat centre in the hypothalamus which reacts to
changes in blood temperature and afferent stimuli from the skin, by controlling cutaneous blood supply and the rate and volume of sweat secretion for evaporation at the surface.
NAIL APPARATUS

Nails (Fig. 7.18) are homologous with the cornified layer of the general epidermis. They consist of compacted, anucleate, keratin-filled squames in two or three horizontal layers. Ultrastructurally, the squames contain closely packed filaments which lie transversely to the direction of proximodistal growth, and are embedded in a dense protein matrix. Unlike the general epidermis, squames are not shed from the nail plate surface. A variety of mineral elements are present in nail, including calcium. Calcium is not responsible for the hardness of nail: this is determined by the arrangement and cohesion of the layers of squames, and their internal fibres. The water content of nail is low, but nail is 10 times more permeable to water than the general epidermis. The softness and elasticity of the nail plate is related to its degree of hydration.
The nail apparatus consists of the nail plate, proximal and lateral nail folds, nail matrix, nail bed and hyponychium.

**Nail plate**
The nail plate is embedded within the proximal and lateral nail folds. It is approximately rectangular in shape and is mostly convex in both longitudinal and transverse axes: there is considerable inter- and intra-individual variation (Fig. 7.18). The thickness of the plate increases proximodistally from about 0.7 mm to 1.6 mm: the terminal thickness varies between individuals. The surface of the nail plate may show fine longitudinal ridges, and its undersurface is grooved by corresponding ridges in the nail bed. Disturbances of growth pattern or disease may lead to transverse ridging or grooves, and minute trapped air bubbles may produce white flecks. These defects move distally with growth of the plate.

The nail plate arises from compacted cornified epithelial cells derived from the dorsal, intermediate and ventral nail matrices. It is densely adherent to the matrices on its undersurface, but becomes a free structure distal to the onychodermal band, where it separates from the nail bed. The dorsal aspect of the nail plate originates from the more proximal regions of the germinal matrix, i.e. dorsal and intermediate matrices, whereas the deeper, volar aspect of the plate originates from the ventral matrix.

Nail folds

The sides of the nail plate are bordered by lateral nail folds which are continuous with the proximal fold (Fig. 7.18). The lateral nail folds enclose the lateral free edges of the nail plate and are bounded by the attachment of the skin to the lateral aspect of the distal phalanx margin and the lateral nail. The proximal nail fold provides the visible proximal border to the nail apparatus. It consists of two epidermal layers, superficial and deep, separated by a core of dermis. The epidermis of the superficial layer lacks hair follicles and epidermal ridges: its cornified distal margin extends over the nail plate for a little distance as the cuticle or eponychium. The deep layer merges with the nail matrix.

The eponychium is bounded by the fascial attachment of the skin to the base of the distal phalanx, distal to the insertion of the extensor tendon, and its distal free edge. It adheres to the dorsal aspect of the nail plate and overlies the root of the nail.

Nail matrix

The nail matrix is the main source of the nail plate, and it can be divided into three parts. Proximally, the dorsal matrix is defined as the volar surface (undersurface) of the proximal nail fold. The intermediate matrix (germinal matrix) starts where the dorsal matrix folds back on itself and extends as far as the distal portion of the lunule. The ventral matrix (sterile matrix) is the remainder of the nail bed: it starts at the distal border of the lunule and ends at the hyponychium.
The matrix epithelium consists of typical basal and prickle cell layer keratinocytes, among which are scattered melanocytes and Langerhans cells. Cornified cells of the dorsal and ventral aspects of the matrix are steadily extruded distally to form the nail plate: the proximal 50% of the nail matrix contributes 80% of the nail plate. This process continues into the nail bed at the distal edge of the lunule, which is formed where the distal portion of the ventral matrix underlies the nail plate.

The lunule is pale, opaque and convex and is more prominent in the thumb than the other digits. It is not known why the lunule is so pale compared with the more distal translucent pink nail bed. The lack of colour may reflect the thickness of the epidermis in the lunule and/or a paucity of capillaries in the dermis of the lunule.

*Nail bed*

The nail bed epidermis extends from the distal margin of the lunule to the hyponychium. The distal margin of the nail bed, at which point the nail plate becomes free of the nail bed, is called the onychodermal band. The surface of the nail bed is ridged and grooved longitudinally, corresponding to a similar pattern on the undersurface of the nail plate. This results in a tight interlocking of the two which prevents the invasion of microbes and the impaction of debris underneath the nail. The epidermis of the nail bed is thin and lacks a stratum granulosum. It consists of two to three layers of nucleated cells which lack keratohyalin granules, and a thin cornified layer which moves distally with the growing nail plate. It contains an occasional sweat gland distally.

The dermis of the nail bed is anchored to the periosteum of the distal phalanx without any intervening subcutaneous layer. It forms a distinct compartment, which means that infections of the nail bed, or other local causes of a rise in pressure (e.g. haematoma) may cause severe pain which is only relieved by excision of part or all of the nail plate. The dermis is richly vascularized. The blood vessels are arranged longitudinally and display numerous glomus bodies, which are encapsulated arteriovenous anastomoses involved in the physiological control of peripheral blood flow in relation to temperature (see Ch. 6 and Ch. 50). The dermis is well-innervated, and contains numerous sensory nerve endings, including Merkel endings and Meissner's corpuscles.

Nail bed cells differentiate towards the nail plate, and contribute to its thickness ventrally.

*Hyponychium*

The hyponychium is the area under the free nail between the onychodermal band proximally and the distal groove. It is an epidermal ridge which
demarcates the junction between the finger pulp and the subungual structures.

**Growth of nail**

Nail growth is determined by the turnover rate of the matrix cells, which varies with digit, age, environmental temperature and season, time of day, nutritional status, trauma and various diseases. Generally, its speed is related to the length of the digit, being fastest (approximately 0.1 mm per day) in the middle finger of the hand, and slowest in the little finger. Fingernails grow three to four times faster than toenails, quicker in summer than in winter, and faster in the young than in the old. A fingernail grows out in about 6 months, whereas a toenail is replaced, on average, in 18 months.

Genetic keratin disorders (Irvine & McLean 1999) may lead to nail dystrophies such as pachyonychia, where the nails become grossly thickened.
The metabolic demands of the skin are not great, and yet, under normal conditions, its blood flow exceeds nutritional requirements by 10 times, and may amount to 5% of the cardiac output. This is because the cutaneous circulation has an important thermoregulatory function, and is arranged so that its capacity can be increased or decreased rapidly by as much as 20 times, in response to the required loss or conservation of heat.

The blood supply to the skin originates from three main sources, the direct cutaneous system, the musculocutaneous system and the fasciocutaneous system. The direct cutaneous system of vessels is derived from the main arterial trunks and accompanying veins. Vessels course in the subcutaneous fat parallel to the skin surface, and are confined to certain areas of the body, e.g. the supraorbital artery, the superficial circumflex iliac artery and the dorsalis pedis artery. The musculocutaneous perforators arise from the intramuscular vasculature, pass through the surface of the muscle, and pierce the deep fascia to reach the skin by spreading out in the subcutaneous tissues. The fasciocutaneous system consists of perforating branches from deeply located vessels (deep to the deep fascia) which pass along intermuscular septa and then fan out at the level of the deep fascia to reach the skin. Examples include the fasciocutaneous perforating vessels from the radial and ulnar arteries.

The direct cutaneous vessels, the musculocutaneous perforators and the fasciocutaneous perforators each contribute to six anastomosing horizontal reticular plexi of arterioles (Fig. 7.19) which have vascular connections between them and which ultimately provide the blood supply to the skin. Three plexi are located in the skin itself and supply all elements including the sweat glands and pilosebaceous units. The subpapillary plexus is located at the junction of the papillary and reticular layers of the dermis. It gives off small branches which form capillary loops in the dermal papillae (usually one loop per papilla) which are perpendicular to the skin surface (Fig. 7.1, Fig. 7.4, Fig. 7.20). The reticular dermal plexus is located in the middle portion of the dermis and is primarily venous. The deep dermal plexus is located in the deepest part of the reticular dermis and on the undersurface of the dermis. The close association between arteriolar and venous plexi permits exchange of heat between blood in vessels at different temperatures flowing in opposite directions (counter-current heat exchange).
Fig. 7.19  Vascular supply to the skin. A. Note the various horizontal plexuses fed by direct cutaneous, fasciocutaneous and musculocutaneous arteries. B. Higher magnification of vascular supply.

The remaining three plexi are the subcutaneous plexus, and two plexi associated with the deep fascia. The deep fascia has a plexus on its deep surface and a more extensive plexus on its superficial surface. This arrangement is much more pronounced in the limbs than it is in the trunk.

The general structure and arrangement of the microvasculature is described in detail in Ch. 6, and so only features particular to skin will be considered here. In the deeper layers of the dermis, arteriovenous anastomoses are common, particularly in the extremities (hands, feet, ears, lips, nose), where, as glomera, they are surrounded by thick muscular coats. Under autonomic vasomotor control, these vascular shunts, when relaxed, divert blood away from the superficial plexus and so reduce heat loss, while at the same time ensuring some deep cutaneous circulation and preventing anoxia of structures such as nerves. Extensive capillary anastomoses are present. Generally, cutaneous blood flow is regulated according to thermoregulatory need, and also, in some areas of the body, according to emotional state. In very cold conditions, the peripheral circulation is greatly reduced by vasoconstriction, but intermittent spontaneous vasodilatation results in periodic increases in temperature which prevent cooling to the level at which frostbite might occur. This is thought to be due to a direct effect of oxygen lack on the arteriolar constrictor muscle, rather than to a neural influence.

The lymphatics of the skin, as elsewhere, are small terminal vessels which collect interstitial fluid and macromolecules for return to the circulation via larger vessels. They also convey lymphocytes, Langerhans cells and macrophages to regional lymph nodes. They begin as blind-ended, endothelial-lined tubes or loops just below the papillary dermis. These drain into a superficial plexus below the subpapillary venous plexus, which drains via collecting vessels into a deeper plexus at the junction of the reticular dermis and subcutis, and this, in turn, drains into the larger subcutaneous channels.
INNERVATION

Skin is a major sensory surface, with regional variations in sensitivity to different stimuli. It has a rich nerve supply, which is also concerned with autonomic functions, particularly related to thermoregulation. Cutaneous sense provides information about the external environment through receptors responsive to stimuli which may be mechanical (rapid or sustained touch, pressure, vibration, stretching, bending of hairs, etc.), thermal (hot and cold), or noxious (perceived as itching, discomfort or pain). Pacinian corpuscles subserve deep pressure and vibrational sensation, and are located deep in the dermis or in the hypodermis, particularly of the digits. Meissner's corpuscles are located in dermal papillae, close to the dermo-epidermal junction, and are sensitive to touch sensation. These receptors are particularly suited to detecting shape and texture during active exploratory touch as employed most skillfully by readers of Braille text.

The primary input is transmitted by neurones whose cell bodies lie in the spinal and cranial ganglia (see p. 55), and whose myelinated or unmyelinated axons are terminally distributed, mainly within the dermis. Efferent autonomic fibres are unmyelinated and noradrenergic or cholinergic. They innervate the arterioles, arrector pili muscles, and the myoepithelial cells of sweat and apocrine glands. In the scrotum, labia minora, perineal skin and nipples they also supply smooth muscle fasciculi of the dermis and adjacent connective tissue. Except in the nipples and genital area, activity of the autonomic efferent nerves is mainly concerned with regulation of heat loss by vasodilation and vasoconstriction, sweat production, and pilo-erection (although this is a minor function in humans).

On reaching the dermis, nerve fasciculi branch extensively to form a deep reticular plexus which serves much of the dermis, including most sweat glands, hair follicles and the larger arterioles. Many small fasciculi pass from this plexus to ramify in another superficial papillary plexus at the junction between the reticular and papillary layers of the dermis. Branches from this pass superficially into the papillary layer, ramifying horizontally and vertically, and terminate either in relation to encapsulated receptors, or as terminals reaching the level of the basal lamina. In some instances, they enter the epidermis as free endings, responsive to light pressure and touch sensation or to nociceptive stimuli. As these latter fasciculi terminate, they lose their epineurial and perineurial sheaths, leaving Schwann cell axonal complexes or naked axons enveloped by basal lamina, in direct contact with the matrix. These naked distal axonal terminals may be vulnerable to pathogens entering via a skin abrasion. The structure and classification of sensory endings are described in detail Chapter 3.

The segmental arrangement of the spinal nerves is reflected in the sensory supply of the skin: a dermatome is the area supplied by all the cutaneous
branches of an individual spinal nerve through its dorsal and ventral rami (see Ch. 15 and Fig. 15.12). Typically, dermatomes extend round the body from the posterior to the anterior median line. The upper half of each zone is supplemented by the nerve above, the lower half by the nerve below. Dermatomes of adjacent spinal nerves overlap markedly, particularly in the segments least affected by development of the limbs.
DEVELOPMENT OF SKIN AND SKIN APPENDAGES

Skin is developed from the surface ectoderm and its underlying mesenchyme. Surface ectoderm gives rise to the cornifying general surface epidermis and its appendages, the pilosebaceous units, sweat glands and nail units, depending on interactions with the mesenchyme. Interactions between ectoderm and mesenchyme also give rise to the internal epithelium of the buccal cavity and the teeth and the nasal epithelia. The differentiated descendants of ectodermal cells are keratinocytes. Immigrant cells of different developmental origin constitute an important component of the epithelial sheet formed by the keratinocytes. The non-keratinocytes are melanocytes and Merkel cells derived from the neural crest, Langerhans cells of bone-marrow origin, and lymphocytes.

The dermis, composed of irregular connective tissue and some of the connective tissue sheaths of peripheral nerves, is derived from somatopleuric mesenchyme (in the limbs and trunk), and possibly somitic mesenchyme (covering the epaxial musculature), and from neural crest (in the head). Angiogenic mesenchyme gives rise to the blood vessels of the dermis. Nerves and associated Schwann cells, of neural crest origin, enter and traverse the dermis to reach their peripheral terminations during development.

EPIDERMIS AND APPENDAGES

General (interfollicular) epidermis

In the first 4–5 weeks, embryonic skin consists of a single layer of ectodermal cells overlying a mesenchyme containing cells of stellate dendritic appearance interconnected by slender processes and sparsely distributed in a loosely arranged microfibrillar matrix (Fig. 7.21). The interface between ectoderm and mesenchyme, known as the basement membrane zone (BMZ), is an important site of mutual interactions upon which the maintenance of the two tissues depends, both in prenatal and postnatal life. Ectodermal cells, which characteristically contain glycogen deposits, contact each other at gap and tight junctions. The layer so formed soon develops into a bilaminar epithelium, and desmosomes also appear. The basal germinative layer gives rise to the definitive postnatal epidermis, and the superficial layer to the periderm, a transient layer confined to fetal life. The periderm maintains itself, expresses different keratin polypeptides, and grows by the mitotic activity of its own cells, independent of those of the germinative layer. Originally flattened, the periderm cells increase in depth: the central area containing the nucleus becomes elevated and projects as a globular elevation towards the amniotic cavity. The plasma membrane develops numerous surface microvilli with an extraneous coat of glycosaminoglycans, and cytoplasmic vesicles become prominent deep to it. These developments reach a peak over the period 12–18 weeks, at which time the periderm is a major source of the amniotic fluid to which it may contribute glucose; it also has an absorptive function. From about 20 weeks onwards, the globular protrusions become undermined and pinched off to float free in the amniotic fluid. The now flattened periderm cells undergo a type of terminal differentiation to form what is regarded as a temporary protective layer for the underlying developing epidermis proper, against an amniotic fluid of changing composition as a result of the accumulation of products of fetal renal excretion. Up to parturition, periderm squames continue to be cast off into the amniotic fluid, and they contribute to the vernix.
caseosa, a layer of cellular debris which covers the fetal skin at birth.

Proliferation in the germinative layer leads to a stratified appearance with successive layers of intermediate cells between it and the periderm. From an early stage, cells of all layers are packed with glycogen granules, presumably a source of energy during this early replicative stage of differentiation. Differentiation of these layers is not synchronous throughout all regions of the developing skin, being more advanced cranially than caudally, and progressing on the body from the midaxillary line ventrally. Reduction in glycogen content of the cells is associated with a shift towards biosynthetic activity connected with terminal (cornifying) differentiation, manifested by the presence of different enzymes and expression of keratins. Simple epithelial keratins present from before implantation (K8 and K18) are replaced by typical keratinocyte basal cell keratins (K5 and K14), followed in the first suprabasal cell layer by those of higher molecular weight associated with differentiation (K1 and K10) at 10–12 weeks. This is soon followed by expression of profilaggrin and filaggrin, and the appearance of keratohyalin granules among filamentous bundles of the uppermost intermediate layer cells at approximately 20 weeks. The first fully differentiated keratinocytes appear shortly afterwards. By 24–26 weeks a definite cornified layer exists in some areas, and by 30 weeks or so, apart from some lingering glycogen in intermediate cells, the interfollicular epidermis is essentially similar to its postnatal counterpart (see Holbrook & Odland 1980, for further details).

Non-keratinocytes are present in developing epidermis from about 8 weeks' gestation. Langerhans cells can be seen in the epidermis by 5–6 weeks and are fully
differentiated by 12–14 weeks. Their numbers increase at least partially by mitotic division \textit{in situ}, but at 6 months are only 10–20\% of those in the adult. It is not known if the Langerhans cell functions in immune surveillance in fetal skin. Melanocytes, of neural crest origin, are present in the bilaminar epidermis of cephalic regions as early as 8 weeks. By 12–14 weeks they can reach a density of 2300 per mm\(^2\) reducing to 800 per mm\(^2\) just before birth. Keratinocytes regulate the final ratio between themselves and melanocytes via growth factors, cell surface molecules and other signals. Fetal melanocytes produce melanized melanosomes and transfer them to keratinocytes: these are intrinsic activities clearly independent of ultraviolet (UV) irradiation, and suggest functions of melanin other than photoprotection.

Merkel cells originate from migratory neural crest cells (Szeder et al 2003) and begin to appear in the epidermis of the palm and sole of the foot between 8 and 12 weeks, and later in association with some hairs and with dermal axonal–Schwann cell complexes.

\textbf{Pilosebaceous unit}

Pilosebaceous units develop at about 9 weeks, first in the regions of the eyebrows, lips, and chin, and at progressively later stages elsewhere, proceeding caudally. The first rudiment is a crowding of cells in the basal layer of the epidermis, the hair placode, adjacent to a local concentration of mesenchymal cells which will become the dermal papilla. Further proliferation and elongation of the cells leads to a hair germ, which protrudes downwards into the mesenchyme in association with the primitive dermal papilla during weeks 13–15. With continued downward growth in a slanted direction, the hair germ becomes a hair peg, and when its bulbous lower end envelops the dermal papilla it is known as a bulbous peg. Melanocytes are individually present at the hair peg stage, and abundantly so and quite active in the bulbous peg. At this stage (approximately week 15) two or three swellings appear on the posterior wall. The uppermost is the rudiment of the apocrine gland (present only in some follicles), the middle forms the sebaceous gland and the lower one is the bulb, to which the arrector pili muscle (arising from underlying mesenchyme) later becomes attached, and where it is believed the main reservoir of hair follicle stem cells resides. The cells of the lowermost region of the bulb, the matrix, divide actively and produce a pointed hair cone. This grows upwards to canalize a developing hair tract, along which the fully formed hair, derived by further differentiation of cells advancing from the matrix, reaches the surface at approximately week 18 of gestation.

Sebaceous glands develop independently of hair follicles in the nostrils, eyelids (as tarsal glands) and in the anal region. Apocrine sweat glands are formed at the same time as eccrine (merocrine) sweat glands and are at first distributed widely over the body. Their number diminishes from 5 months' gestation, producing the distribution seen in the adult.

Hairs produced prenatally are called lanugo hairs; they are short and downy, lack a medulla, and in certain parts of the body are arranged in a vortex-like manner into tracts. Late in pregnancy, lanugo hairs are replaced by vellus hairs, and these in turn by intermediate hairs, which are the predominant type until puberty. New follicles do not develop in postnatal skin.

\textit{Eccrine sweat glands}
Eccrine (merocrine) sweat glands are one type of sudoriferous gland. Sweat gland rudiments appear in the second and third months as cell buds associated with the primary epidermal ridges of the finger and toe pads of terminal digits. They elongate into the dermis and by 16 weeks the lower end begins to form the secretory coil, within which, by 22 weeks, secretory and myoepithelial cells are evident. The solid cord of cells connecting the coil to the epidermis becomes the intradermal duct, and the lumina of both are formed by dissolution of desmosomal contacts between the cells. The intraepidermal duct is foreshadowed by a coiled column of concentrically arranged inner and outer cells, within which, by fusion of lysosomal vacuoles, a lumen is formed which opens on the surface at 22 weeks. As with hair follicles, no new eccrine sweat glands develop postnatally. Emotional sweating, detected by skin conductance changes, occurs in preterm infants from 29 weeks’ gestational age.

**Epidermal ridges**

The epidermal ridges are foreshadowed as regularly spaced small downgrowths of epidermal cells which appear in finger and toe pads during the second and third months. They are known as primary epidermal ridges, separated by corresponding dermal ridges. In the fifth month secondary ridges develop, the pattern becomes evident on the surface, and is finalized through further remodelling postnatally.

**Nails**

Fields of proliferative ectoderm appear on the tips of the terminal segments of the digits. They progressively reach a dorsal position, where at approximately 9 weeks, a flattened nail field limited by proximal, distal, and lateral nail grooves is apparent. The nail field ultimately forms the nail bed, and the primordium of the nail is formed of a wedge of cells which grows diagonally, proximally and deeply into the mesenchyme from the proximal groove towards the underlying terminal phalanx. The deeper cells of this wedge form the primordium of the matrix which gives rise to the nail plate. The latter emerges from under a, now proximal, nail fold at about 14 weeks and grows distally over an already keratinized nail bed. The nail matrix is usually considered to have dorsal and ventral (intermediate) components, but there are conflicting opinions as to the extent to which each contributes to the nail, both in ontogeny and postnatally: it is generally agreed that the ventral matrix contributes the major part. It has been claimed that the nail bed additionally contributes up to 20% of the postnatal nail plate, but embryological studies to date are not clear on this matter. Most texts state that keratohyalin is not involved in the cornification of nail. However, up to at least 16 weeks, the dorsal matrix granular layer cells which contribute cornified cells to the nail plate and eponychium (cuticle) contain typical keratohyalin granules, and the cells of the ventral matrix next to the nail plate contain single and compound granules similar to those present in granular layer cells of oral epithelia. Similar granules have been reported in matrix cells of postnatal human toenail.

At 20 weeks, the nail plate entirely covers the nail field (nail bed), now limited distally by a distal ridge, which, when the plate projects beyond the tip, becomes the hyponychium beneath it. At birth, the microstructure of the main nail unit components is similar to that postnatally; the nail is long and overhanging, and easily falls off during cleansing.

**Abnormalities of the epidermis**
Anomalous development of the epidermis and its derivatives is relatively common. Excessive or diminished growth, or even complete absence, may affect sebaceous or sudoriferous glands and hair, either locally or generally. Similarly, the epidermis may be excessively pigmented (melanism). Excessive production of the cornified layer leads to ichthyosis. A naevus or mole is a benign proliferation of melanocytes in the basal layer of the epidermis. Ectodermal dysplasia is a rare condition characterized by fine blond and scanty hair, reduced or absent eyelashes and eyebrows. The skin has deficient sweat and sebaceous glands. Teeth are usually peg- or cone-shaped, and absence of major salivary glands may occur. For information on keratin disorders, see Irvine & McLean 1999.
DERMIS

The embryonic dermis is far richer in cells than the adult dermis, and many of these mesenchymal cells are involved in an essential signalling dialogue which regulates ectodermal differentiation. The mesenchymal cells underlying the surface ectoderm and early bi- and trilaminar epidermis contact each other by slender processes to form an intercommunicating network. They secrete a matrix which is rich in ions, water, and macromolecules, proteoglycan/glycosaminoglycans, fibronectin, collagenous proteins of various types and elastin. Further development of these intrinsic components involves the differentiation of individual cell types, fibroblasts, endothelial cells, mast cells, etc. and the assembly of matrix components into organized fibrillar collagen fibres and elastic fibres. During embryogenesis, the matrix is heterogeneous with regard to its biochemical and macromolecular components. The main glycosaminoglycans of embryonic and fetal skin are glycuronic acid and dermatan sulfate. Collagens type I, III, V, and VI are distributed more or less uniformly regardless of fetal age, and there are some local concentrations of III and V, the levels of which are higher than in postnatal skin. Collagens type IV and VII are found predominantly in the BMZ.

The progressive morphological differentiation of the dermis involves its separation from the subcutis at about the third month; changes in composition and size of collagen fibrils and their organization into bundles amongst which cells become relatively fewer; downgrowth of epidermal appendages; the organization of nervous and vascular plexuses, and the relatively late appearance of elastic networks. The papillary and reticular regions are said to be evident as early as 14 weeks, but the overall organization of the dermis continues postnatally.

Vascular supply and lymphatic drainage

The dermal vasculature is generally thought to be developed in situ by transformation of angiogenic mesenchymal cells. Closed endothelial-lined channels containing nucleated red cells are present by 6 weeks underneath the ectoderm, and by the eighth week are arranged in a single plane parallel to the epidermis: they will ultimately form the subpapillary plexus. A second deeper horizontal plexus is evident by 50–70 days. Both plexuses extend by budding as development proceeds, and they give rise to the final patterns of arterioles, venules and capillaries which are established shortly after birth. Pericytes also develop from mesenchymal cells. Lymphatic vessels are formed by mesenchymal cells which become organized to enclose pools of proteinaceous fluid leaking from the developing capillaries.

Innervation
Sensory cutaneous nerves (axons and Schwann cells) are derived by outgrowth from the neural crest (via dorsal root ganglia). Motor fibres to vessels and glands arise from cells of sympathetic ganglia. As individual parts of the embryo grow, the nerves grow and lengthen with them. Small axons are present superficially at a stage when the epidermis is bilaminar, and by 8 weeks gestation there is already a functioning cutaneous plexus. By the fourth gestational month, the dermal plexuses are very richly developed, and Meissner and Pacinian corpuscles have appeared. The outer lamellar cells of Pacinian corpuscles in the dermis are homologous with the perineurium, but the source of the laminar cells of the Meissner corpuscle is unclear.
EPITHELIAL–MESENCHYMAL INTERACTIONS IN DEVELOPING SKIN

Epidermal–mesenchymal (dermal) interactions at the BMZ occur during development and throughout life. At the ectodermal stage, the BMZ consists of the basal plasma membrane of an ectodermal cell, paralleled on its cytoplasmic side by various cytoskeletal filaments, and beneath it, by a layer (0.1–0.2 µm) of microfibrillar-amorphous material deposited by the cell. At the bilaminar stage, a definite continuous lamina densa is present, separated from the basal plasma membrane by a lamina lucida traversed by loosely fibrillar material: similar filaments extend from the lamina densa into the mesenchymal matrix.

Hemidesmosomes begin to appear at 8 weeks as stratification starts, and anchoring fibrils at 9–10 weeks. By the end of the third month the basic morphology of the interfollicular BMZ is essentially similar to that of the postnatal BMZ.

Laminin and collagen type IV are present in the developing basal lamina at 6 weeks, and bullous pemphigoid antigen (BPAG, in hemidesmosomes) and anchoring fibril proteins are expressed later. These immunocytochemical and morphological observations are of importance for prenatal diagnosis of genetically determined diseases, e.g. epidermolysis bullosa. The basal lamina provides a physical supporting substrate and attachment for the developing epidermis, and is thought to be selectively permeable to macromolecules and soluble factors regulating epidermal–dermal morphogenetic interactions.
The surface area of the skin increases with growth. It has been estimated that the surface area of a premature neonate weighing 1505 g is approximately 1266 cm$^2$, whereas a neonate of 2980 g has a surface area of 2129 cm$^2$. The skin of the neonate is thinner than that of older infants and children. It cornifies over a period of 2–3 weeks which provides protection; however, in the premature infant the thin epidermal layer allows absorption of a variety of substances, e.g. chlorhexidine and boric acid and also permits a significantly higher transepidermal water loss than occurs in full term neonates. At birth the skin is richly vascularized by a dense subepidermal plexus. The mature pattern of capillary loops and of the subpapillary venous plexus is not present at birth but develops as a result of capillary budding with migration of endothelia at some sites and the absorption of vessels from other sites. Some regions mature faster than others. With the exceptions of the palms, soles and nail beds, the skin of the neonate has almost no papillary loops. It has a disordered capillary network which becomes more orderly from the second week when papillary loops appear; defined loops are not present until the fourth or fifth week, and all areas possess loops by 14–17 weeks postnatally.

Neonates exhibit a regional sequence of eccrine gland maturation. The earliest sweating occurs on the forehead, followed by the chest, upper arm and, later, more caudal areas. Acceleration of maturation of the sweating response occurs in premature babies after delivery.
NATURAL SKIN CREASES AND WRINKLES

SKIN LINES

The surface of the skin and its deeper structures show various linear markings, seen as grooves, raised areas and preferred directions of stretching. Some of these are clearly evident in intact skin, others only appear after some sort of intervention.

Surface pattern lines, tension lines and skin creases

Externally visible skin lines are related to various patterns of epidermal creasing, ridge formation, scarring and pigmentation. A simple lattice pattern of lines occurs on all major areas of the body other than the thick skin of volar and plantar surfaces. The lattice pattern typically consists of polygons formed by relatively deep primary creases visible to the naked eye, which are irregularly divided by finer secondary creases into triangular areas (Fig. 7.22, Fig. 7.23). These, in turn, are further subdivided by tertiary creases limited to the cornified layer of the epidermis, and, finally, at the microscopic level, by quaternary lines which are simply the outlines of individual squames (Fig. 7.7). Apart from the quaternary lines, all the others increase the surface area of the skin, permit considerable stretching and recoil and distribute stresses more evenly. Details of the pattern vary according to the region of the body; e.g. on the cheek the primary creases radiate from the hair follicles, on the scalp they form hexagons, while on the calf and thigh they form parallelograms. There is a relationship between type of pattern and local skin extensibility.
Fig. 7.22  The surface of hairless skin from the palm of the hand, showing epidermal friction (papillary) ridges and larger flexure lines (left).
Wrinkle lines

Wrinkle lines are caused by contraction of underlying muscles and are usually perpendicular to their axis of shortening. On the face they are known as lines of expression, and with progressive loss of skin elasticity due to ageing, they become permanent. Occupational lines are creases produced by repeated muscular contractions associated with particular trades or skills. Contour lines are lines of division at junctions of body planes, e.g. the cheek with the nose, and lines of dependency are produced by the effect of gravity on loose skin or fatty tissue, e.g. the creases associated with the pendulous fold beneath the chin in older age.

Flexure (joint) lines

Flexure (joint) lines are major markings found in the vicinity of synovial joints, where the skin is attached strongly to the underlying deep fascia (Fig. 7.22). They are conspicuous on the flexor surfaces of the palms, soles, and digits, and in combination with associated skin folds, they facilitate movement. The skin lines do not necessarily coincide with the associated underlying joint line. For example, the flexure lines demarcating the extended fingers from the palm lie approximately half an inch distal to the metacarpophalangeal joints, the positions of which are more closely related to the distal palmar crease (heart-line of palmistry). The patterns of flexure lines on the palms and soles may vary and are to some extent genetically determined. In Down
Papillary ridges

Papillary ridges are confined to the palms and soles and the flexor surfaces of the digits, where they form narrow parallel or curved arrays separated by narrow furrows (Fig. 7.24, Fig. 7.25). The apertures of sweat ducts open at regular intervals along the summit of each ridge. The epidermal ridges correspond to an underlying interlocking pattern of dermal papillae, an arrangement which helps to anchor the two layers firmly together. The pattern of dermal papillae determines the early development of the epidermal ridges. This arrangement is stable throughout life, unique to the individual, and therefore significant as a means of identification. The ridge pattern can be affected by certain abnormalities of early development, including genetic disorders such as Down syndrome, and skeletal malformations such as polydactyly. Absence of epidermal ridges is extremely rare. Functionally, epidermal ridges increase the gripping ability of hands and feet, preventing slipping. The great density of tactile nerve endings beneath them means that they are also important sensory structures.
Fig. 7.24  The palmar aspect of a terminal phalanx to show fingerprint ridges. Note interphalangeal flexure line (below).
The analysis of ridge patterns by studying prints of them (fingerprints) is known as dermatoglyphics and is of considerable forensic importance. Measurable parameters include the frequency of ridges in particular patterns and the disposition of tri-radii, which are junctional areas where three sets of parallel ridges meet. Fingerprint ridge patterns can be separated into three major types (Fig. 7.24), arches (5%), loops (70%), and whorls (25%). Arches have no tri-radii, loops have one tri-radius, and whorls have two or more. Whorl finger patterns are more common on the right hand, and males generally have more whorls and fewer arches than females, in whom the ridges are relatively narrower. The frequency of individual patterns varies with particular fingers. Similar patterns are seen on the toes.

The precise positions, numbers and ridge-counts associated with the tri-radii have an inherited basis: in general the genetics are multifactorial and highly complex. However, the total ridge-count of all 10 digits of the hand appears to have a simpler inheritance.
If the mechanical demands placed on the skin are greater than the skin creases and the dermis can accommodate, the lateral cohesion of dermal collagen fibres is disrupted, and there is associated haemorrhage and cellular reaction, and eventually, formation of poorly vascularized scar tissue. These changes can be termed intrinsic, to distinguish them from scars formed by external wounding. Sites of dermal rupture are visible externally as lines or striae. They are initially pink in colour, later widen and become a vivid purple or red (striae rubrae), and eventually fade, becoming paler than the surrounding intact skin (striae albae). They develop on the anterior abdominal wall of some women in pregnancy when they are termed striae gravidarum (stretch marks).

Variation in pigmentation can also produce externally visible lines on the surface of the skin. Futcher's or Voigt's lines mark differences in pigmentation between the darker extensor and paler flexor surfaces of the arms, and occur along the anterior axial lines, extending from the sternum to the wrist. They are more common in darker-skinned races.

**Lines detectable after manipulation or incision**

In certain regions of the body, surgical wounds heal with a better and less conspicuous scar if they are lying in a particular direction. This finding is related to a number of factors including skin tension and naturally formed wrinkle lines. Skin is normally under tension and the direction in which this is greatest varies regionally. Tension is dependent on the protrusion of underlying structures, the direction of underlying muscles, and on joint movements. Many anatomists and surgeons have therefore attempted to produce a body map to indicate the best direction in which to make an elective incision to obtain the most aesthetic scar. These maps frequently differ, especially in the region of the face. Out of the multitude of described cleavage lines, the most commonly referred to are relaxed skin tension lines (RSTLs), Langer's lines, and Kraissl's lines (Borges 1984). Of these, the RSTLs and Kraissl's lines are probably more appropriate lines for surgical incision.

**Relaxed skin tension lines**

Relaxed skin tension lines (RSTLs) are those which correspond to the directional pull (which forms furrows) when the skin is relaxed: they do not always correspond to wrinkle lines. The tension across the RSTL is constant even during sleep but can be altered (increased, decreased or abolished) by underlying muscle contraction. The direction of the RSTLs can be determined by pinching the skin in different directions. Pinching at right angles to the RSTLs will result in fewer and higher furrows than pinching parallel to these lines.

**Lines of Langer and Kraissl**

Langer punctured the skin of cadavers with a circular awl and noted the subsequent elliptical-shaped openings. By connecting the long axis of these holes, he produced the cleavage lines named after him. These lines represent skin tension in rigor mortis but frequently do not relate to the lines of choice in making elective incisions. Indeed, Langer's lines often run at right angles to the RSTLs on the face.

Kraissl's lines are essentially exaggerated wrinkle lines obtained by studying the loose skin of elderly faces whilst contracting the muscles of facial expression. These lines
for the most part correspond to RSTLs, but slight variation exists on the face, especially on the lateral side of the nose, the lateral aspect of the orbit, and the chin. For further information on lines of Langer and Kraissl, see Chapter 29.

**Blaschko lines**

Blaschko's lines refer to the way in which patterns of naevi and related dermatological pathologies are distributed or develop along certain preferred cutaneous pathways. They do not appear to correspond to vascular or neural elements of the skin, and may be related to earlier developmental boundaries of a ‘mosaic’ nature.
AGE-RELATED SKIN CHANGES

Two main factors, chronological and environmental, are involved in skin ageing. Chronological changes are physiological or intrinsic in origin. A major environmental factor is chronic exposure to the sun, referred to as photoageing: emphasis is laid upon differences between the two because photoageing is to some extent preventable.

**Intrinsic ageing**

From about the third decade onwards there are gradual changes in the appearance and mechanical properties of the skin which reflect natural ageing processes. These become very marked in old age. Normal ageing is accompanied by epidermal and dermal atrophy, which result in some changes in the appearance, microstructure and function of the skin. Alterations include wrinkling, dryness, loss of elasticity, thinning and a tendency towards purpura on minor injury. Epidermal atrophy is expressed by general thinning and loss of the basal rete pegs with flattening of the dermo-epidermal junction, and this results in a reduction in contact area between the two which may affect epidermal nutrition. Flattening of the junction decreases resistance to shear, leading to poor adhesion of epidermis and its separation following minor injury. The thickness of the cornified layer is not reduced in old age, and its permeability characteristics seem little affected. Epidermal proliferative activity and rate of cell replacement decline with age, being reduced by up to 50% in elderly skin. Synthesis of vitamin D is also reduced. After middle age there is a 10–20% decline in the number of melanocytes, and Langerhans cells become sparser, which is associated with a reduction in immune responsiveness. Depigmentation and loss of hair, and some local increases (eyebrows, nose and ears in males, and face and upper lip in females) are commonly observed. Alterations in non-keratinocytes may be aggravated by chronic exposure to UV irradiation.

Dermal changes are mainly responsible for the appearance of aged skin, its stiffness, flaccidity and wrinkling, and loss of extensibility and elasticity. Its general thickness diminishes as a result of the decline in collagen synthesis by a reduced population of fibroblasts, though the relative proportion of type III collagen increases. Senile elastosis is a degenerative condition of collagen which may be partly due to excessive exposure to sun. Vascularization of the skin is reduced, the capillary loops of the dermal papillae are particularly affected, and the tendency towards small spontaneous purpuric haemorrhages indicates a general fragility of the cutaneous microvasculature. A decrease in sensitivity of sensory perception associated with some loss of specialized receptors occurs.

**Photoageing**
Photoageing is a major concern because of an association with epidermal cancer. The effects of chronic sun exposure on melanocytes (stimulatory) and Langerhans cells (destructive) are thought to be connected with the increasing incidence of malignant melanoma in some groups of individuals, where reduction in tumour monitoring activity by Langerhans cells may be a factor.
CUTANEOUS WOUND HEALING AND SCARRING

The end-point of healing of mammalian skin wounds is usually scar formation. Cutaneous scars result from injury to both the epidermis and underlying dermis; while the epidermis largely regenerates, dermal architecture is abnormal after repair and the undulating pattern of rete ridges at the dermo-epidermal junction is not reproduced. It is not known why scarring occurs. Scar tissue is biomechanically inferior to unwounded skin. Appendages such as hair follicles, sebaceous and sweat glands that are derived from the epidermis do not regenerate after wounding. It is possible that humans evolved to close wounds rapidly, at the expense of perfect regeneration.

The molecular biology of cutaneous repair involves the coordination of numerous cell types, signalling molecules and matrix proteins. Many such factors are pleiotropic in their effects and it is the complex balance of such mediators, rather than their individual action, that determines events in wound repair. Wound healing is often considered in four overlapping temporal phases, namely haemostasis, inflammation, proliferation and remodelling (Fig. 7.26). These events will be discussed separately for clarity, although this is an artificial division of the complex, inter-related processes that constitute the wound healing response. For further reading, see Miller & Nanchahal (2005).
HAEMOSTASIS

Wounding causing vascular injury initiates fibrin-fibronectin clot formation. The clot consists of platelets (promoted to aggregate by fibrillar collagens type I and III) embedded in a mesh of cross-linked fibrin and fibronectin fibres. It serves as a haemostatic plug, protects the denuded wound with a temporary physical shield, and forms a provisional matrix through and over which cells migrate during the repair process. The clot also acts as a reservoir of growth factors and cytokines, which are released as platelets de-granulate, and contribute to inflammatory cell recruitment.
INFLAMMATION

Neutrophils and monocytes are recruited to wound sites within minutes of injury by a variety of chemotactic signals, including complement factors, bacterial polysaccharides, cytokines and growth factors such as tumour necrosis factor (TNF)-α, interleukin (IL)-1, platelet-derived growth factor (PDGF), transforming growth factor (TGF)-α and TGF-β1,2, basic fibroblast growth factors (bFGF/FGF-2), serotonin, and monocyte chemotactic protein-1 (MCP-1).

Neutrophils act against contaminating bacteria. Monocytes differentiate into macrophages that phagocytose not only pathogenic organisms, but also expended neutrophils, cell and matrix debris. Both neutrophils and macrophages act as a further source of cytokines and growth factors to amplify stimuli already present in the wound site. Macrophages are also a source of additional factors such as TGFβ, FGF and vascular endothelial growth factor (VEGF) that activate resident fibroblasts, endothelial cells and keratinocytes, which in turn are central to the processes of re-epithelialization and formation of granulation tissue, as discussed below.
PROLIFERATION

The proliferation phase of wound healing involves re-epithelialization and granulation tissue formation which take place more or less simultaneously.

Re-epithelialization

Re-epithelialization begins within hours of wounding as a result of keratinocyte migration and proliferation from the wound edges and skin appendages. Cytokines such as epidermal growth factor (EGF), FGF, keratinocyte growth factor (KGF, FGF-7), insulin like growth factor-1 (IGF-1) and TGFα are released by activated fibroblasts and keratinocytes, and stimulate the re-epithelialization process. The mechanisms of keratinocyte migration are not fully understood, although disruption of desmosomes and hemidesmosomes, extracellular matrix contact, formation of cytoplasmic actin filaments and degradation of the fibrin matrix are all likely to be important. There is evidence that keratinocyte expression of matrix metalloproteinases (MMPs) is associated with re-epithelialization. During this phase of cutaneous wound healing, keratinocyte proliferation is thought to be upregulated after migration has started; dividing and migrating cells are found in the first suprabasal as well as basal keratinocyte layers. MMP activity is regulated by the production of tissue inhibitors of MMPs (TIMPs) and a relative imbalance, with upregulation of certain MMPs, may be associated with impaired wound healing. When the denuded wound surface has been covered by a monolayer of keratinocytes, migration ceases. A stratified epidermis with an underlying basal lamina is re-established from the margins of the wound inwards. Anchoring fibrils linking the basal lamina to the underlying connective tissue mark neo-epidermal maturity.

Granulation tissue formation

The term granulation tissue refers to the macroscopic appearance of wound connective tissue, which appears pink and granular. It contains numerous capillaries that invade the initial wound clot and become organized into a microvascular network (angiogenesis), together with the cells and molecules necessary to stimulate neo-matrix deposition. Angiogenesis is a complex process, promoted by dynamic interactions between endothelial cells, angiogenic cytokines (including FGF-2, VEGF (mainly from keratinocytes), PDGF and TGFβ1,2) and the extracellular matrix environment.

Electron microscope studies have shown that the epidermis, basal lamina and papillary dermis all develop on the surface of the granulation tissue. Wounds that fail to granulate do not heal satisfactorily, suggesting that granulation tissue formation is a key aspect of wound repair. Excessive granulation is also associated with delayed re-epithelialization.
Activated fibroblasts in the healing wound proliferate in response to growth factors, notably TGFβ1, IGF-1, PDGF, FGF and EGF. Within 72 hours of injury, these fibroblasts synthesize components of the new extracellular matrix, which are deposited in an orderly sequence. The neo-matrix initially includes fibronectin and hyaluronic acid which form a provisional substratum for cellular migration. Fibronectin acts as an initiation site for collagen fibrillogenesis, and as anchorage for myofibroblasts to effect wound contraction. Hyaluronic acid forms a highly hydrated matrix that is easily penetrated by migrating cells. Ultimately this and other neo-matrix components are replaced, first by collagen type III, and subsequently by collagen type I, which imparts strength to the mature scar (see remodelling, below). Non-structural proteins such as tenascin are also found in the neo-matrix of healing wounds and provide signals that orchestrate the repair process.

Cellularity decreases during the evolution of granulation tissue into a mature scar (and during other phases of wound healing) mainly as a result of apoptosis.
REMODELLING

Remodelling of the extracellular matrix is important throughout the wound healing process and persists for some time after closure of the defect. Fibroblasts are responsible for matrix remodelling as well as deposition. Initially they replace hyaluronic acid in the neo-matrix with sulphated proteoglycans, such as decorin, biglycan, and versican, which contribute to tissue resilience. Increased wound strength coincides with new collagen deposition. Approximately three weeks after injury, collagen breakdown and synthesis equilibrate; subsequent more gradual increases in wound strength reflect collagen remodelling, with the formation of intermolecular cross links and larger collagen bundles. Scar maturation is associated with proportional increases in collagen type I relative to collagen type III. Collagen fibres of the dermis in scars are arranged in an irregular fashion and scarred skin only reaches a maximum tensile strength of about 70% of unwounded skin.

Wound contraction

An important part of remodelling is wound contraction. Once granulation tissue has been laid down, a proportion of activated fibroblasts transform into myofibroblasts, which play a key role in wound contraction: they are thought to generate forces that pull normal dermal and adipose tissue into the wound defect.
SCARLESS WOUND HEALING

Wounds heal with reduced or absent scarring in certain circumstances, notably cutaneous wounds in the early fetus. The development of a major inflammatory response at a wound site appears to be a significant determinant of whether scarring occurs. Scarless fetal wound healing is characterized by fewer inflammatory cells (which are less differentiated than their adult counterparts and which remain in the wound for a shorter time), rapid re-epithelialization, reduced angiogenesis and restoration of the connective tissue architecture in which collagen is arranged in the normal reticular pattern.

An ontogenic transition period, during which cutaneous healing changes from scar-free to scar-forming, has been identified in the third trimester of gestation. Studies of this transition period have led to the identification of molecules of key importance in the scarring process; the most extensively characterized factor to date is TGFβ. Three mammalian TGFβ isoforms have been identified, TGFβ-1, -2 and -3. Comparisons of fetal scar-free and adult scar-forming wounds show that TGFβ-1 and -2 are not present in fetal wounds, suggesting that scarless wound healing is associated with TGFβ-3 activity, rather than TGFβ-1 and -2. The β-1 and -2 isoforms are dominant in fetal, neonatal and adult wounds that form scars. The main sources of TGFβ-3 are fibroblasts and keratinocytes, whilst TGFβ-1, and -2 are produced from degranulating platelets and subsequently from monocytes and macrophages: the low levels of TGFβ-1 seen in fetal wounds have been attributed to a relative lack of platelet de-granulation and fibrin clot formation.
SKIN GRAFTS AND FLAPS

A graft is a piece of tissue which has been detached from its blood supply and therefore needs to regain a blood supply from the bed in which it is placed in order to survive. In contrast, a flap is a piece of tissue which is surgically raised and transferred from one location in the body to another whilst maintaining its blood supply, which enters the base (pedicle) of the flap when it is transplanted.

GRAFTS

Grafts can be composed of skin, fat, fascia or bone, either separately or together as a composite piece of tissue. Skin grafts can be either full thickness grafts or split thickness grafts. Full thickness grafts consist of the epidermis and the full thickness of the dermis. Split thickness grafts consist of the epidermis and a variable quantity of the dermis. An essential difference is that the donor site following the harvest of a full thickness graft has no epidermal elements from which new skin can regenerate. These grafts therefore tend to be taken from sites of the body where the donor defect can be primarily closed. The donor site from split thickness grafting contains adnexal remnants (hair follicles in particular) which have the propensity to divide and regenerate new epidermis and so resurface the donor defect.

Revascularization of grafts is dependent on early and direct connection between host and graft vessels (inosculation), before which graft survival depends on fluid absorption (imbibition). Revascularization, which occurs as early as 48 hours, is by both anastomosis, whereby the severed ends of preexisting graft vessels link up with vessels of the underlying wound bed; and neovascularization, which involves the de novo angiogenic ingrowth of vessels from the wound bed into the graft. During the first two weeks, blood vessels from the recipient invade the graft edges along previous vascular channels in the direction of an ischaemic stimulus, whereas native graft vasculature begins to regress. Endothelial progenitor cells appear to play an important role in blood vessel formation, attracted by ischaemic gradients. Inosculation occurs, restoring blood flow to the graft microcirculation. By the start of the third week, complete blood flow in the graft vasculature has been established and in the absence of a continuing ischaemic stimulus, neovascularization ends.
FLAPS

Flaps are named according to the type of tissue transferred, e.g. a fasciocutaneous flap contains skin and fascia, and a musculocutaneous flap contains both muscle and the overlying skin, whereas a skin flap, fascial flap or a muscle flap contain only the separate elements that their names imply. The blood supply to a skin flap can be randomly orientated, which limits the flap length to breadth proportions to no more than 2 : 1 (except on the face, where longer flaps can be raised). Much longer skin flaps can be raised elsewhere if the blood supply to the flap is a direct cutaneous artery and vein: these are called axial pattern flaps.

A free flap (free tissue transfer) is a specific type of flap in which the tissue, whether skin, fascia, muscle, bone or a combination of these, is completely removed from its original location in the body along with a single identifiable artery and vein and transferred to a remote site. The blood vessels in the flap are anastomosed to vessels located in the new site using microsurgical techniques. This often allows for greater flexibility in performing reconstructive surgery. (The arterial perforators in the lower limb are described in Ch. 79.)

Section 2 – EMBRYOGENESIS

CHAPTER 8 – Preimplantation development

Understanding the spatial and temporal developmental processes that take place within an embryo as it develops from a single cell into a recognizable human is the challenge of embryology. The control of these processes resides within the genome: fundamental questions remain concerning the genes and interactions involved in development.

STAGING OF EMBRYOS

For the purposes of embryological study, prenatal life is divided into an embryonic period and a fetal period. The embryonic period covers the first 8 weeks of development (weeks following ovulation and fertilization resulting in pregnancy). The ages of early human embryos have previously been estimated by comparing their development with that of monkey embryos of known postovulatory ages. Because embryos develop at different rates and attain different final weights and sizes, a classification of human embryos into 23 stages occurring during the first 8 weeks after ovulation was developed most successfully by Streeter (1942), and the task was continued by O'Rahilly & Müller (1987). An embryo was initially staged by comparing its development with that of other embryos. On the basis of correlating particular maternal menstrual histories and the known developmental ages of monkey embryos, growth tables were constructed so that the size of an embryo (specifically, the greatest length) could be used to predict its presumed age in postovulatory days (synonymous to postfertilizational days). O'Rahilly & Müller (2000) emphasize that the stages are based on external and internal morphological criteria and are not founded on length or age. Ultrasonic examination of embryos in vivo has necessitated the revision of some of the ages related to stages, and embryos of stages 6–16 are now thought to be up to 3 to 5 days older than the previously used embryological estimates (O'Rahilly & Müller 1999). Within this staging system, embryonic life commences with fertilization at stage 1; stage 2 encompasses embryos from two cells, through compaction and early segregation, to the appearance of the blastocele. The developmental processes occurring during the first 10 stages of embryonic life are shown in Fig. 8.1.
Much of our knowledge of the early developmental processes is derived from experimental studies on amniote embryos, particularly the chick, mouse and rat. Figure 8.2 shows the comparative timescales of development of these species and human development up to stage 12. The size and age, in postovulatory days, of human development from stage 10 to stage 23 is given in Fig. 8.3.
In developmental biology, evidence concerning the nature of developmental processes has come mainly from studies in vertebrate embryos, most commonly amniote embryos of the chick, mouse, and rat. This chart illustrates the comparative timescale of development of these animals and the human.
Information on developmental age after stage 23 (8 weeks postovulation) is shown in Fig. 14.3, where the developmental staging used throughout this text is juxtaposed with the obstetric estimation of gestation that is used clinically. A critique of staging terminology and the hazards of the concurrent use of gestational age and embryonic age is given in Chapter 14; sizes and ages of fetuses towards the end of gestation are illustrated in Fig. 14.7.
FERTILIZATION

The central feature of reproduction is the fusion of the two gamete pronuclei at fertilization. In humans the male gametes are spermatozoa, which are produced from puberty onwards. Female gametes are released as secondary oocytes in the second meiotic metaphase, usually singly, in a cyclical fashion. The signal for the completion of the second meiotic division is fertilization, which stimulates the cell division cycle to resume, completing meiosis and extruding the second polar body (the second set of redundant meiotic chromosomes).

Fertilization normally occurs in the ampullary region of the uterine tube, probably within 24 hours of ovulation. Very few spermatozoa reach the ampulla to achieve fertilization. They must undergo capacitation, a process which is still incompletely understood, and which may involve modifications of membrane sterols or surface proteins. They traverse the cumulus oophorus and corona radiata, then bind to specific glycoprotein receptors on the zona pellucida, ZP3 and ZP2. Interaction of ZP3 with the sperm head induces the acrosome reaction, in which fusion of membranes on the sperm head releases enzymes, such as acrosin, which help to digest the zona around the sperm head, allowing the sperm to reach the perivitelline space. In the perivitelline space, the spermatozoon fuses with the oocyte microvilli, possibly via two disintegrin peptides in the sperm head and integrin in the oolemma (Fig. 8.4 and Fig. 8.5A).
Fig. 8.4 Fertilization pathway: a succession of steps. After a sperm binds to the zona pellucida, the acrosome reaction takes place (see detail at top). The outer acrosomal membrane (blue), an enzyme-rich organelle in the anterior of the sperm head, fuses at many points with the plasma membrane surrounding the sperm head. Then those fused membranes form vesicles, which are eventually sloughed off from the head, exposing the acrosomal enzymes (red). The enzymes digest a path through the zona pellucida, enabling the sperm to advance. Eventually, the sperm meets and fuses with the secondary oocyte plasma membrane and this triggers cortical and zona reactions. First, enzyme-rich cortical granules in the oocyte cytoplasm release their contents (yellow) into the zona pellucida, starting at the point of fusion and progressing right and left. Next, in the zona reaction, the enzymes modify the zona pellucida, transforming it into an impenetrable barrier to sperm as a guard against polyspermy (multiple fertilization).
Fusion of the sperm with the oolemma causes a weak membrane depolarization and leads to a calcium wave, which is triggered by the sperm at the site of fusion and crosses the egg within 5–20 seconds. The calcium wave amplifies the local signal at the site of sperm–oocyte interaction and distributes it throughout the oocyte cytoplasm. The increase in calcium concentration is the signal that causes the oocyte to resume cell division, initiating the completion of meiosis II and setting off the developmental programme that leads to embryogenesis. The pulses of intracellular calcium that occur every few minutes for the first few hours of development also trigger the fusion of cortical granules with the oolemma. The cortical secretory granules release an enzyme that hydrolyses the ZP3 receptor on the zona pellucida and so prevents other sperm from binding and undergoing the acrosome reaction, thus establishing the block to polyspermy. The same cortical granule secretion may also modify the vitelline layer and oolemma, making them less susceptible to sperm–oocyte fusion and providing a further level of polyspermy block.

The sperm head undergoes its protamine → histone transition as the second polar body is extruded. The two pronuclei grow, move together and condense in preparation for syngamy and cleavage after 24 hours (Fig. 8.5B). Nucleolar rRNA, and perhaps some mRNA, is synthesized in pronuclei. A succeeding series of cleavage divisions produces eight even-sized blastomeres at 2.5 days, when embryonic mRNA is transcribed.

Several examples of cells which contain male and female pronuclei, termed ootids, have been described. Pronuclear fusion as such does not occur: the two pronuclear envelopes disappear and the two chromosome groups move together to assume positions on the first cleavage spindle. No true zygote containing a membrane-bound nucleus is formed.

The presence of the pronuclei from both parental origins is crucial for spatial organization and the controlled growth of cells, tissues and organs. In the mouse, embryos in which the paternal pronucleus has been removed and replaced with a second maternal pronucleus develop to a relatively advanced state (25 somites), but with limited development of the trophoblast and extraembryonic tissues. In contrast, embryos in which the maternal pronucleus has been replaced by a second paternal pronucleus develop very poorly, forming embryos of only six to eight somites, but with extensive trophoblast. Thus it seems that the maternal genome is relatively more important for the development of the embryo, whereas the paternal genome is essential for the development of the extraembryonic tissues that would lead to placental formation.

This functional inequivalence of homologous parental chromosomes is called parental
imprinting. The process causes the expression of particular genes to be dependent on their parental origin: some genes are expressed only from the maternally inherited chromosome and others from the paternally inherited chromosome. The genes involved are called imprinted genes. The requirement for both parental genomes is limited to a subset of the chromosomes. Uniparental disomy can arise through meiotic and mitotic non-disjunction events, and results in individuals who are completely disomic or who exhibit mosaicism of disomic and non-disomic cells. If imprinted genes reside on the affected chromosomes, then the uniparental disomic cells will either express a double dose of the gene or have both copies repressed. For example, the gene encoding the embryonal mitogen insulin-like growth factor II is expressed from the paternally inherited chromosome, and repressed when maternally inherited.

In vitro fertilization

Fertilization of human gametes in vitro (IVF) is a successful way of overcoming most forms of infertility. Controlled stimulation of the ovaries (e.g. pituitary downregulation using gonadotrophin-releasing hormone superactive analogues, followed by stimulation with purified follicle stimulating hormone or urinary menopausal gonadotrophins) enables many preovulatory oocytes (often 10 or more) to be recruited and matured, and then aspirated either by laparoscopy or transvaginally using ultrasound guidance, 34–38 hours after injection of human chorionic gonadotrophin (which is given to mimic the luteinizing hormone surge). These oocytes are then incubated overnight with motile spermatozoa in a specially formulated culture medium, to achieve successful fertilization in vitro. In cases of severe male-factor infertility, in which there are insufficient normal spermatozoa to achieve fertilization in vitro, individual spermatozoa can be directly injected into the oocyte in a process known as intracytoplasmic injection of sperm, which is as successful as routine in vitro fertilization. In cases in which there are no spermatozoa in the ejaculate, suitable material can sometimes be directly aspirated from the epididymis or surgically retrieved from the testes, and the extracted sperm are then used for intracytoplasmic injection of sperm. It is also now possible, in some cases, to test embryos for the presence of a particular genetic or chromosomal abnormality in a process known as preimplantation genetic diagnosis. A sample (biopsy) is removed from either the oocyte polar body, the embryo itself (a blastomere) or the blastocyst (small piece of trophectoderm), and subjected to a specific genetic test. Unaffected embryos can then be identified for transfer to the patient. Embryos that are surplus to immediate therapeutic requirements can also be cryopreserved in liquid nitrogen for later use. Propanediol or dimethylsulphoxide is used as a cryoprotectant for early embryos, and glycerol is used for blastocysts. Conception rates per cycle using ovarian stimulation, in vitro fertilization and successive transfers of fresh and cryopreserved embryos, far outstrip those obtained during non-assisted conception.
PREIMPLANTATION DEVELOPMENT

Cleavage

The first divisions of the zygote are termed cleavage. They distribute the cytoplasm approximately equally among daughter blastomeres, so although the cell number of the preimplantation embryo increases, its total mass actually decreases slightly (Fig. 8.6). The cell cycle is quite long, the first two cell cycles being around 24 hours each, thereafter reducing to 12–18 hours. Cell division is asynchronous and daughter cells may retain a cytoplasmic link through much of the immediately subsequent cell cycle via a midbody, as a result of the delayed completion of cytokinesis. No centrioles are present until 16 to 32 cells are seen, but amorphous pericentriolar material is present and serves to organize the mitotic spindles, which are characteristically more barrel-than spindle-shaped at this time.
All cleavage divisions after fertilization are dependent upon continuing protein synthesis. In contrast, passage through the earliest cycles, up to eight cells, is independent of mRNA synthesis. Thereafter, experimental inhibition of transcription blocks further division and development, indicating that activation of the embryonic genome is required. There is also direct evidence for the synthesis of embryonically encoded proteins at this time. As the genes of the embryo first become both active and essential, the previously functional maternally derived mRNA is destroyed. However, protein made on these maternal templates does persist at least during blastocyst growth. Spontaneous developmental arrest of embryo culture in vitro seems to occur during the cell cycle of gene activation, but it is not caused by total failure of that activation process. Early cleavage, up to the formation of eight cells, requires pyruvate or lactate as metabolic substrates, but thereafter more glucose is metabolized and may be required.

The earliest time at which different types of cells can be identified within the cleaving embryo is when 8 to 16 cells are present. Up to the formation of eight cells, cells are essentially spherical, touch each other loosely, and have no specialized intercellular junctions or significant extracellular matrix; the cytoplasm in each cell is organized in a radially symmetric manner around a centrally located nucleus. Once eight cells have formed, a process of compaction occurs. Cells flatten on each other to maximize...
intercellular contact, initiate the formation of gap and focal tight junctions, and radically reorganize their cytoplasmic conformation from a radially symmetric to a highly asymmetric phenotype. This latter process includes the migration of nuclei towards the centre of the embryo, the redistribution of surface microvilli and an underlying mesh of microfilaments and microtubules to the exposed surface, and the localization of endosomes beneath the apical cytoskeletal mesh. As a result of the process of compaction, the embryo forms a primitive protoepithelial cyst, which consists of eight polarized cells, in which the apices face outward and basolateral surfaces face internally. The focal tight junctions, which align to become increasingly linear, are localized to the boundary between the apical and basolateral surfaces. Gap junctions form between apposed basolateral surfaces and become functional.

The process of compaction involves the cell surface and the calcium dependent cell–cell adhesion glycoprotein, E-cadherin (also called L-CAM or uvomorulin). Neutralization of its function disturb all three elements of compaction. The entire process can function in the absence of both mRNA and protein synthesis. Post-translational controls are sufficient and seem to involve regulation through protein phosphorylation. Significantly, although E-cadherin is not synthesized and present on the surface of cleaving blastomeres, it first becomes phosphorylated when eight cells are visible, at the initiation of compaction.

The process of compaction is important for the generation of cell diversity in the early embryo. As each polarized cell divides, it retains significant elements of its polar organization, so that its daughter cells inherit cytocortical domains, the nature of which reflects their origin and organization in the original parent cell in the eight-celled embryo. Thus, if the axis of division is aligned approximately at right angles to the axis of cell polarity, the more superficially placed daughter cell inherits all the apical cytocortex and some of the basolateral cytocortex and is polar, whereas the more centrally placed cell inherits only basolateral cytocortex and is apolar. In contrast, if the axis of division is aligned approximately along the axis of the cell polarity, two polar daughter cells are formed. In this way, two-cell populations are formed in the 16-cell embryo that differ in phenotype (polar, apolar) and position (superficial, deep). The number of cells in each population in any one embryo will be determined by the ratio of divisions along, and at right angles to, the axis of eight-cell polarity. The theoretical and observed limits of the polar to apolar ratio are 16 : 0 and 8 : 8. The outer polar cells contribute largely to the trophectoderm, whereas the inner apolar cells contribute almost exclusively to the inner cell mass in most embryos.

In cleavage the generation of cell diversity, to either trophectoderm or inner cell mass, occurs in the 16-cell morula and precedes the formation of the blastocyst. During the 16-cell cycle, the outer polar cells continue to differentiate an epithelial phenotype, and display further aspects of polarity and intercellular adhesion typical of epithelial cells, while the inner apolar cells remain symmetrically organized. During the next cell division (16 to 32 cells), a proportion of polar cells again divide differentiatively as in the previous cycle, each yielding one polar and one apolar progeny, which enter the trophectoderm and inner cell mass lineages, respectively. Although differentiative division at this time is less common than at the 8- to 16-cell transition, it has the important function of regulating an appropriate number of cells in the two tissues of the blastocyst. Thus, if differentiative divisions were relatively infrequent at the 8- to 16-cell transition, they will be more frequent at the 16- to 32-cell transition, and vice versa.
After division to the 32 cells, the outer polar cells complete their differentiation into a functional epithelium, display structurally complete zonular tight junctions and begin to form desmosomes. The nascent trophectoderm engages in vectorial fluid transport in an apical to basal direction to generate a cavity that expands in size during the 32- to 64-cell cycles and converts the ball of cells, the morula, to a sphere, the blastocyst (Fig. 8.7). Once the blastocyst forms, the diversification of the trophectoderm and inner cell mass lineages is complete, and trophectoderm differentiative divisions no longer occur. In the late blastocyst, the trophectoderm is referred to as the trophoblast, which can be divided into polar trophoblast, which lies in direct contact with the inner cell mass, and mural trophoblast, which surrounds the blastocyst cavity (Fig. 8.8).
Fig. 8.7 Human embryos. Formation of a morula and blastocyst within the zona pellucida and blastocyst hatching from the zona pellucida. A, A ball of cells, the morula, with the cells undergoing compaction; B, the blastocyst cavity is developing and the inner cell mass can be seen on one side of the cavity; C, the blastocyst is beginning to hatch from the zona pellucida.

Fig. 8.8 Human blastocyst nearly completely hatched from the zona pellucida. The blastocyst can now expand to its full size.

**Blastocyst**

The blastocyst ‘hatches’ from its zona pellucida at 6–7 days, possibly assisted by an enzyme similar to trypsin (Figs 8.7C, 8.8). Trophoblast oozes out of a small slit; many
embryos form a figure-of-eight shape bisected by the zona pellucida, especially if it has been hardened during oocyte maturation and cleavage. Such half-hatching could result in the formation of identical twins. Hatched blastocysts expand and differentiation of the inner cell mass proceeds (Fig. 8.8).

The outer cells of the blastocyst, the trophoblast or trophectoderm, are flattened polyhedral cells, which possess ultrastructural features typical of a transporting epithelium. The trophoblast covering the inner cell mass is the polar trophoblast and that surrounding the blastocyst cavity is the mural trophoblast. The free, unattached blastocyst is assigned to stage 3 of development at approximately 4 days postovulation, whereas implantation (before villus development) occurs within a period of 7–12 days postovulation and over the next two stages of development. Even at this early stage, cells of the inner cell mass are already arranged into an upper layer (i.e. closest to the polar trophoblast), the epiblast, which will give rise to the embryonic cells, and a lower layer, the hypoblast, which has an extraembryonic fate. Thus the dorsoventral axis of the developing embryo and a bilaminar arrangement of the inner cell mass are both established at or before implantation. (The earliest primordial germ cells may also be defined at this stage.)

Attachment to the uterine wall

On the sixth postovulatory day, the blastocyst adheres to the uterine mucosa and the events leading to the specialized, intimate contact of trophoblast and endometrium begin. Implantation, which is the term used for this complicated process, includes the following stages: dissolution of the zona pellucida; orientation and adhesion of the blastocyst onto the endometrium; trophoblastic penetration into the endometrium; migration of the blastocyst into the endometrium; spread and proliferation of the trophoblast, which envelops and specifically disrupts and invades the maternal tissues.

The site of implantation is normally in the endometrium of the posterior wall of the uterus, nearer to the fundus than to the cervix, and may be in the median plane or to one or other side. Implantation may occur elsewhere in the uterus, or in an extruterine or ectopic site. Implantation near the internal os results in the condition of placenta praevia, with its attendant risk of severe antepartum haemorrhage.

Ectopic implantation

The conceptus may be arrested at any point during its migration through the uterine tube and implant in its wall. Previous pelvic inflammation damages the tubal epithelium and may predispose to such delay in tubal transport. The presence of an intrauterine contraceptive device or the use of progesterone-based oral contraceptives may also predispose to ectopic pregnancy, probably because of alteration in the normal tubal transport mechanisms.

Nidation of the embryo as an ectopic pregnancy most frequently occurs in the wider ampullary portion of the uterine tube, but may also occur in the narrow intramural part or even in the ovary itself. Most ectopic pregnancies are anembryonic, although the continuing growth of the trophoblast will produce a positive pregnancy test, and may cause rupture of the uterine tube and significant intraperitoneal haemorrhage. Ectopic pregnancies with a live embryo are the most dangerous, because they grow rapidly and may be detected only when they have eroded the uterine tube wall and
surrounding blood vessels, as early as 8 weeks of pregnancy. Similarly, cornual ectopics (in the intramural part of the tube) may present with catastrophic haemorrhage, because there is a substantial blood supply in the surrounding muscularis.

Ovarian or abdominal pregnancies are exceptionally rare. Although some are presumed to have been caused by fertilization occurring in the vicinity of the ovary (primary), most are probably caused secondarily and result from an extrusion of the conceptus through the abdominal ostium of the tube.

Apart from their important clinical implications, these conditions emphasize the fact that the conceptus can implant successfully into tissues other than a normal progestational endometrium. Prolonged development can occur in such sites and is usually terminated by a mechanical or vascular accident and not by a fundamental nutritive or endocrine insufficiency or by an immune maternal response. Abdominal implantation may occur on any organ, e.g. bowel, liver, omentum. If such a pregnancy continues, this makes removal of the placenta at delivery or abortion hazardous as a result of haemorrhage, and consequently the placenta is usually left in situ to degenerate spontaneously.

**Twinning**

Spontaneous twinning occurs once in about every 80 births. Monozygotic twins arise from a single ovum fertilized by a single sperm. At some stage up to the establishment of the axis of the embryonic area and the development of the primitive streak, the embryonic cells separate into two parts, each of which gives rise to a complete embryo. The process of hatching of the blastocyst from the zona pellucida may result in constriction of the emerging cells and separation into two discrete entities. There is a gradual decrease in the average thickness of the zona pellucida with increasing maternal age, which may be causally related to the increase in frequency of monozygotic twinning with increased maternal age. The resultant twins have the same genotype, but the description ‘identical twins’ is best avoided, since most monozygotic twins have differences in phenotypes. Late separation of twins from a single conceptus may result in conjoined twins; these may be equal or unequal as in acardia. After twinning, monozygotic embryos enter a period of intense catch-up growth. Despite starting out at half the size, each twin embryo or fetus is of a size comparable to a singleton fetus in the second trimester of pregnancy, but declines in relative size in the last 10 weeks of pregnancy. The sex of monozygotic twins will be the same. Monoamniotic, monochorionic, monozygotic twins are most likely to be female, as are acardiac twins. The male:female ratio for all monozygotic twins is 0.487, and for monoamniotic, monochorionic twins it is 0.231.

Dizygotic twins represent the most frequent form of twinning. They result from multiple ovulations, which can be induced by gonadotrophins or drugs commonly used in patients with infertility. Dizygotic twins may be different sexes; like-sex pairs are more common. The male: female ratio is 0.518. Multiple births greater than twinning, such as triplets or quadruplets, can arise from multiple ovulations, or from a single ovum, or both. It is most likely to be seen in women treated with drugs to stimulate ovulation.

The range of separation of twin embryos is reflected in the separation of the extraembryonic membranes. The types of placentation that can occur are shown in
Fig. 8.9. Monoamniotic, monochorionic placentae are associated with the greatest perinatal mortality (50%), caused both by entanglement of the umbilical cords impeding the blood supply and by various vascular shunts between the placentae, which may divert blood from one fetus to the other. Artery–artery anastomoses are the most common, followed by artery–vein anastomoses. If the shunting of blood across the placentae from one twin to the other is balanced by more than one vascular connection, development may proceed unimpaired. However, if this is not the case, one twin may receive blood from the other, leading to cardiac enlargement, increased urination and hydramnios in the recipient, and anaemia, oligohydramnios and atrophy in the donor.

Fig. 8.9  Relationships of the extraembryonic membranes in different types of twinning. A, Diamnionic, dichorionic separated; i.e. separation of the first two blastomeres results in separate implantation sites. B, Diamnionic, dichorionic fused; here the chorionic membranes are fused, but the fetuses occupy separate choria. C, Diamnionic, monochorionic; reduplication of the inner cell mass can result in a single placenta and chorionic sacs, but separate amniotic cavities. D, Monoamnionic, monochorionic; duplication of the embryonic axis results in two embryos sharing a single placenta, chorion and amnion. E, Incomplete separation of the embryonic axis results in conjoined twins. F, Unequal division of the embryonic axis or unequal division of the blood supply may result in an acardiac monster.
Dizygotic twins have either completely separate chorionic sacs or sacs that have fused. Such placentae are separated by four membranes, two amnia and two choria; in addition these placentae have a ridge of firmer tissue at the base of the dividing membranes, caused by the abutting of two expanding placental tissues against each other.
FORMATION OF EXTRAEMBRYONIC TISSUES

The earliest developmental processes in mammalian embryos involve the production of those extraembryonic structures that will support and nourish the embryo during development. Production of these layers begins before implantation is complete. At present it is unclear where the extraembryonic cell lines arise. The trophoblast was considered to be a source, but evidence now points to the inner cell mass as the site of origin. Figure 8.1 shows the sequence of development of various tissues in the early embryo.

Epiblast and amniotic cavity

Epiblast cells, which are closest to the implanting face of the trophoblast, have a definite polarity, being arranged in a radial manner with extensive junctions near the centre of the mass of cells, supported by supranuclear organelles. A few epiblast cells are contiguous with cytotrophoblast cells; apart from this contact a basal lamina surrounds what is initially a spherical cluster of epiblast cells, and isolates them from all other cells. Those epiblast cells adjacent to the hypoblast become taller and more columnar than those adjacent to the trophoblast, and this causes the epiblast sphere to become flattened and the centre of the sphere to be shifted towards the polar trophoblast. Amniotic fluid accumulates at the eccentric centre of the now lenticular epiblast mass, which is bordered by apical junctional complexes and microvilli. As further fluid accumulates, an amniotic cavity forms, roofed by low cuboidal cells that possess irregular microvilli. The cells share short apical junctional complexes and associated desmosomes and rest on an underlying basal lamina. The demarcation between true amnion cells and those of the remaining definitive epiblast is clear. The columnar epiblast cells are arranged as a pseudostratified layer with microvilli, frequently a single cilium, clefted nuclei and large nucleoli; the cells have a distinct, continuous basal lamina. Cell division in the epiblast tends to occur near the apical surface, causing this region to become more crowded than the basal region. At the margins of the embryonic disc, the amnion cells are contiguous with the epiblast; there is a gradation in cell size from columnar to low cuboidal within a two- to three-cell span (Fig. 8.10; see Fig. 9.1). Further development of the amnion and amniotic fluid is described on pages 180 and 181.

Hypoblast and yolk sac

Hypoblast is the term used to delineate the lower layer of cells of the early bilaminar disc, most commonly in avian embryos. This layer is also termed anterior, or distal, visceral endoderm in the mouse embryo. Just before implantation, the hypoblast consists of a layer of squamous cells that is only slightly larger in extent than the epiblast. The cells exhibit polarity, with apical microvilli facing the cavity of the blastocyst and apical junctional complexes, but they lack a basal lamina. During early implantation, the hypoblast extends
beyond the edges of the epiblast and can now be subdivided into those cells in contact with the epiblast basal lamina, the visceral hypoblast, and those cells in contact with the mural trophoblast, the parietal hypoblast. The parietal hypoblast cells are squamous, they may share adhesion junctions with the mural trophoblast and, rarely, may also share gap junctions. The visceral hypoblast cells are cuboidal; they have a uniform apical surface towards the blastocyst cavity, but irregular basal and lateral regions, with flanges and projections underlying one another and extending into intercellular spaces. There is no basal lamina subjacent to the visceral hypoblast, and the distance between the hypoblast cells and the epiblast basal lamina is variable.

A series of modifications of the original blastocystic cavity develops beneath the hypoblast later than those developing above the epiblast. While the amniotic cavity is enlarging within the sphere of epiblast cells, the parietal hypoblast cells are proliferating and spreading along the mural trophoblast until they extend most of the way around the circumference of the blastocyst, converging towards the abembryonic pole. At the same time, a space appears between the parietal hypoblast and the mural trophoblast that limits the circumference of the hypoblastic cavity. A variety of terms have been applied to the parietal hypoblast layer: extraembryonic hypoblast and later extraembryonic endoderm or the exocoelomic (Heuser's) membrane. The cavity that the layer initially surrounds is termed the primary yolk sac, or alternatively the primary umbilical vesicle. The resultant smaller cavity lined by hypoblast is termed the secondary yolk sac. It has been suggested that it forms in a variety of ways, including cavitation of visceral hypoblast (a method similar to formation of the amnion), rearrangement of proliferating visceral hypoblast and folding of the parietal layer of the primary yolk sac into the secondary yolk sac. Further development of the yolk sac is described on page 180. The visceral hypoblast cells are now believed to be important in many aspects of the early specification of cell lines. The cells induce the formation of the primitive streak, thus establishing the first axis of the embryonic disc. They are also believed to be necessary for successful induction of the head region and for the successful specification of the primordial germ cells. With the later formation of the embryonic cell layers from the epiblast, the visceral hypoblast appears to be sequestered into the secondary yolk sac wall by the expansion of the newly formed embryonic endoderm beneath the epiblast. Hypoblastic cells remain beneath the primitive streak: their experimental removal causes multiple embryonic axes to form.

After the formation of the secondary yolk sac, a diverticulum of the visceral hypoblast, the allantois, forms towards one end of the embryonic region and extends into the local extraembryonic mesoblast. It passes from the roof of the secondary yolk sac to the same plane as the amnion. Further development of the allantois is described on page 180.
Extraembryonic mesoblast

By definition, extraembryonic tissues encompass all tissues that do not contribute directly to the future body of the definitive embryo and, later, the fetus. At stage 5, blastocysts are implanted but do not yet display trophoblastic villi (Fig. 8.10); they range from 7 to 12 days in age. A feature of this stage is the first formation of extraembryonic mesoblast, which will come to cover the amnion, secondary yolk sac and the internal wall of the mural trophoblast, and will form the connecting stalk of the embryo with its contained allanto-enteric diverticulum. The origin of this first mesoblastic extraembryonic layer is by no means clear, and it may arise from several sources, including the caudal region of the epiblast, the parietal hypoblast and subhypoblastic cells. The trophoblastic origin of extraembryonic mesoblast is questioned, because there is always a complete basal lamina underlying the trophoblast: the migration of cells out of an epithelium is usually associated with previous disruption of the basal lamina. Certainly, the origin of extraembryonic cells will change over time as new germinal populations are established.

The first mesoblastic extraembryonic layer gives rise to the layer known as extraembryonic mesoblast, arranged as a mesothelium with underlying extraembryonic mesenchymal cells; this also appears to form an extracellular structure corresponding to the magma reticulare, between the mural trophoblast and the primary yolk sac in the stage 5 embryo. Later extraembryonic mesoblast populations mushroom beneath the cytotrophoblastic cells at the embryonic pole, forming the cores of the developing villus stems, and villi (see p. 175) and the angioblastic cells that will give rise to the capillaries within them and the earliest blood cells.

Initially, the extraembryonic mesoblast connects the amnion to the chorion over a wide area. Continued development and expansion of the extraembryonic coelom means that this attachment becomes increasingly circumvented to a connecting stalk, which is a permanent connection between the future caudal end of the embryonic disc and the chorion. The connecting stalk forms a pathway along which vascular anastomoses around the allantois establish communication with those of the chorion.
REFERENCES

IMPLANTATION

Implantation involves the initial attachment of the trophoblastic wall of the blastocyst to the endometrial luminal epithelium. The trophoblast lineage gives rise to three main cell types in the human placenta: the syncytiotrophoblast, which forms the epithelial covering of the villous tree and is the main endocrine component of the placenta; the villous cytotrophoblast cells, which represent a germinative population that proliferate throughout pregnancy and fuse to generate the syncytiotrophoblast; and extravillous trophoblast cells, which are non-proliferative and invade the maternal endometrium. The first two cell lines can be seen from stages 4 and 5 onwards. The cytotrophoblast cells that form the mural and polar trophoblast are cuboidal, and covered externally with syncytiotrophoblast (syncytiotrophoblast), a multinucleated mass of cytoplasm that forms initially in areas near the inner cell mass after apposition of the blastocyst to the uterine mucosa (see Fig. 8.10).

Preimplantation embryos produce matrix metalloproteinases, which mediate penetration of the maternal subepithelial basal lamina by the syncytiotrophoblast. Trophoblast cells express L-selectin (usually seen as a mediator of neutrophil rolling and tethering in inflamed endothelium), and the maternal epithelium upregulates selectin-oligosaccharide-based ligands. Thus, differentiating cytotrophoblast cells appear to use processes that also occur in vasculogenesis and during leukocyte emigration from the blood into the tissues. Flanges of syncytiotrophoblast grow between the cells of the uterine luminal epithelium towards the underlying basal lamina without apparent damage to the maternal cell membranes or disruption of the intercellular junctions. Instead, shared junctions, including tight junctions, are formed with many of the maternal uterine epithelial cells.

Implantation continues with erosion of maternal vascular endothelium and glandular epithelium, and phagocytosis of secretory products, until the blastocyst occupies an uneven implantation cavity in the stroma (interstitial implantation) (Fig. 9.1). In the early postimplantation phase, the maternal surface is resealed by re-epithelialization and the formation of a plug, which may contain fibrin. As the blastocyst burrows more deeply into the endometrium, syncytiotrophoblast forms over the mural cytotrophoblast, but never achieves the thickness of the syncytiotrophoblast over the embryonic pole.
The syncytiotrophoblast secretes numerous hormones; the most well known, human chorionic gonadotrophin (hCG), can be detected in maternal urine from as early as 10 days after fertilization, and forms the basis for tests for early pregnancy. hCG prolongs the life of the corpus luteum, which continues to secrete progesterone and oestrogens during approximately the first two months of pregnancy. Thereafter, these essential hormones are produced by the placenta.

Menstruation ceases on successful implantation. The endometrium, now known as the decidua in pregnancy, thickens to form a suitable nidus for the conceptus. Decidualization of the endometrial stroma may occur without an intrauterine pregnancy, e.g. in the presence of an ectopic pregnancy, after prolonged treatment with progesterone, and in the late secretory phase of a non-conception cycle.

Decidual differentiation is not evident in the stroma at the earliest stages of implantation, and it may not be until a week later that fully differentiated cells are present. During decidualization the interglandular tissue increases in quantity. It contains a substantial population of leukocytes (large granular lymphocytes, macrophages and T cells) distributed amongst large decidual cells: the most numerous are uterine natural killer (NK) cells which accumulate in the endometrium during the secretory phase of the cycle and persist until mid-pregnancy. Decidual cells are mesenchymally derived stromal cells which contain varying amounts of glycogen, lipid, and vimentin-type intermediate filaments in their cytoplasm. They are generally rounded, but their shape may vary depending on the local packing density. They may contain one, two or sometimes three nuclei and frequently display rows of club-like cytoplasmic protrusions enclosing granules. The cells are associated with a characteristic capsular basal lamina. Decidual cells produce a range of secretory products, including insulin-like growth factor binding protein 1 (IGF-BP1) and prolactin, which may be taken up by the trophoblast. These secretions probably play a role in the maintenance and growth of the conceptus in the early part of postimplantational development, and can be detected in amniotic fluid in the first trimester of pregnancy.

Extracellular matrix, growth factors and protease inhibitors produced by the decidua
all probably modulate the degradative activity of the trophoblast and support placental morphogenesis and placental accession to the maternal blood supply. Once implantation is complete, distinctive names are applied to different regions of the decidua (Fig. 9.2). The part covering the conceptus is the decidua capsularis; that between the conceptus and the uterine muscular wall is the decidua basalis (where the placenta subsequently develops); and that which lines the remainder of the body of the uterus is the decidua parietalis. There is no evidence that their respective resident maternal cell populations exhibit site-specific properties.
Fig. 9.2 The gravid uterus in the second month. A placental site precisely in the uterine fundus as indicated in the plan is rather unusual: the dorsal, ventral or lateral wall of the corpus uteri is more usual. The maternal endometrium is now termed decidua; different regions are distinguished.
DEVELOPMENT OF THE PLACENTA

Formation of the human placenta requires a developmental progression which proceeds in a specific order over time; it is specified by the trophoblast, but dependent on the maternal environment for its correct expression. Immunological rejection of the semi-allogenic conceptus does not occur because the syncytiotrophoblast expresses neither Class I nor Class II MHC antigens. By contrast, the invading extravillous trophoblast expresses human leukocyte antigen-G (HLA-G) and -C, which interact with receptors on the uterine NK cells.

As the blastocyst implants, the syncytiotrophoblast invades the uterine tissues, including the glands and walls of maternal blood vessels (Fig. 9.1), and increases rapidly in thickness over the embryonic pole (Fig. 9.3). A progressively thinner layer covers the rest of the wall towards the abembryonic pole. Microvillus-lined clefts and lacunar spaces develop in the syncytiotrophoblastic envelope (days 9–11 of pregnancy) and establish communications with one another. Initially, many of these spaces contain maternal blood derived from dilated uterine capillaries and veins, as the walls of the vessels are partially destroyed. As the conceptus grows, the lacunar spaces enlarge, and become confluent to form an intervillous space.
The projections of syncytiotrophoblast into the maternal decidua are called primary villi. They are invaded first with cytotrophoblast and then with extraembryonic mesenchyme (days 13–15) to form secondary placental villi. Fetal capillaries develop in the mesenchymal core of the villi. The cytotrophoblast within the villi continues to grow through the invading syncytiotrophoblast and makes direct contact with the decidua basalis, forming anchoring villi. Further cytotrophoblast proliferation occurs laterally so that neighbouring outgrowths meet to form a spherical cytotrophoblastic shell around the conceptus (Fig. 9.4). Lateral projections from the main stem villus form true and terminal villi.
As secondary villi form, single mononuclear cells become detached from the distal cytotrophoblast and infiltrate the maternal decidua. These cells are the third line of the original trophoblastic cells. They are found both within and around the spiral arteries in the central area of the placenta and gradually extend laterally, reaching the periphery of the placenta around mid-gestation. They normally extend into the inner third of the uterine myometrium within the central region of the placental bed, but the extent of invasion is progressively shallower towards the periphery. At the same time, cytotrophoblast from the spherical shell penetrates into and migrates along the inner walls of maternal spiral arteries (endovascular extravillous trophoblast) so that by the 18th week it has reached the inner myometrial segments. The interstitially migrating cells invade the spiral arteries from their adventitia. The vessels lose their elastic lamina and consequently their responsiveness to circulating vasoactive compounds. The smooth muscle and associated elastic and collagenous matrix is replaced with non-resistive fibrinoid, an arrangement that permits an expansion of the vessels and as much as a 20-fold increase in the flow of blood into the intervillous space. In normal pregnancies the transformation of spiral arteries into utero-placental arteries is completed around mid gestation. The main aim of these vascular changes appears to be to optimize the distribution of maternal blood into a low-resistance uterine vascular network. Common pregnancy pathologies, including intrauterine growth restriction, pre-eclampsia and spontaneous abortion, are all associated with incomplete vascular remodelling, which probably reflects a failure of penetration by extravillous trophoblast.

With the onset of the embryonic heartbeat, a primitive circulation exists between the embryo and the yolk sac, succeeded later by that between the embryo and the placenta. The formed placenta is composed of a chorionic plate on its fetal aspect and a basal plate on the maternal aspect, and an intervening intervillous space containing villous stems with branches in contact with maternal blood (Fig. 9.4). Since maternal blood bathes the surfaces of the chorion which bound the intervillous space, the human placenta is defined as haemochorial. Different grades of fusion exist between the maternal and fetal tissues in many other mammals (e.g. epitheliochorial,
syndesmochorial, endotheliochorial). The chorion is vascularized by the allantoic blood vessels of the body stalk, and so the human placenta is also termed chorio-allantoic (whereas in some mammals a choriovitelline placenta either exists alone or supplements the chorio-allantoic variety). In addition, the human placenta is defined as discoidal (in contrast to other shapes in other mammals) and deciduate because maternal tissue is shed with the placenta and membranes at parturition as part of the afterbirth.

**Growth of the placenta**

Expansion of the entire conceptus is accompanied by radial growth of the villi and, simultaneously, an integrated tangential growth and expansion of the trophoblastic shell. Eventually each villous stem forms a complex that consists of a single trunk attached by its base to the chorion, from which second and third order branches (intermediate and terminal villi) arise distally. Terminal villi are specialized for exchange between fetal and maternal circulations; each one starts as a syncytial outgrowth and is invaded by cytotrophoblastic cells, which then develop a core of fetal mesenchyme as the villus continues to grow. The core is vascularized by fetal capillaries (i.e. each villus passes through primary, secondary and tertiary grades of histological differentiation). The germinal cytotrophoblast continues to add cells that fuse with the overlying syncytium and so contribute to the expansion of the haemochorial interface. Terminal villi continue to form and branch within the confines of the definitive placenta throughout gestation, projecting in all directions into the intervillous space (Fig. 9.4).

From the third week until about the second month of pregnancy, the entire chorion is covered with villous stems. They are thus continuous peripherally with the trophoblastic shell, which is in close apposition with both the decidua capsularis and the decidua basalis. The villi adjacent to the decidua basalis are stouter, longer and show a greater profusion of terminal villi. As the conceptus continues to expand, the decidua capsularis is progressively compressed and thinned, the circulation through it is gradually reduced, and adjacent villi slowly atrophy and disappear. This process starts at the abembryonic pole, and by the end of the third month, the abembryonic hemisphere of the conceptus is largely denuded. Eventually the whole chorion apposed to the decidua capsularis is smooth and is now termed the chorion laeve. In contrast, the villous stems of the disc-shaped region of chorion apposed to the decidua basalis increase greatly in size and complexity and the region is now termed the chorion frondosum (Fig. 9.3). The chorion frondosum and the decidua basalis constitute the definitive placental site (Fig. 9.2). Abnormalities in this process may account for the persistence of villi at abnormal sites on the chorionic sac and hence the presence of accessory or succenturiate lobes. At term, the placental diameter varies from 200 to 220 mm, the mean placental weight is 470 g, its mean thickness is 25 mm and the total villous surface area is 12–14 m².

Coincidentally with the growth of the embryo and the expansion of the amnion, the decidua capsularis is thinned and distended and the space between it and the decidua parietalis is gradually obliterated. By the second month of pregnancy the three endometrial strata recognizable in the premenstrual phase, i.e. compactum, spongiosum and basale, are better differentiated and easily distinguished. The glands in the spongiosum are compressed and appear as oblique slit-like fissures lined by low cuboidal cells. By the beginning of the third month of pregnancy the decidua
capsularis and decidua parietalis are in contact, while by the fifth month the decidua capsularis is greatly thinned, and during the succeeding months it virtually disappears.

**Chorionic plate**

The chorionic plate is covered on its fetal aspect by the amniotic epithelium, on the stromal side of which is a connective tissue layer carrying the main branches of the umbilical vessels (Fig. 9.4 and Fig. 9.5). Subjacent to this is a diminishing layer of cytotrophoblast and then the inner syncytial wall of the intervillous space. The connective tissue layer is formed by fusion between the mesenchyme-covered surfaces of amnion and chorion: it is more fibrous and less cellular than Wharton's jelly (of the umbilical cord), except near the larger vessels. The umbilical vessels radiate and branch from the cord attachment, with variations in the branching pattern, until they reach the bases of the trunks of the villous stems and then arborize within the intermediate and terminal villi. There are no anastomoses between vascular trees of adjacent stems. The two umbilical arteries are normally joined at, or just before they enter, the chorionic plate, by some form of substantial transverse anastomosis (Hyrtl's anastomosis).

![Fig. 9.5](image)

**Fig. 9.5** The arrangement of the placental tissues from the chorionic plate (fetal side) to the basal plate or decidua basalis (maternal side).

**Basal plate**
The basal plate, from fetal to maternal aspect, forms the outer wall of the intervillous space. The trophoblast and adjacent decidua are enmeshed in layers of fibrinoid and basement membrane-like extracellular matrix to form a complex junctional zone. In different places the basal plate may contain syncytium, cytotrophoblast or fibrinoid matrix, remnants of the cytotrophoblastic shell, and, at the site of implantation, areas of necrotic maternal decidua (the so-called Nitabuch's stria) (Figs 9.4 and 9.5). Nitabuch's stria and the decidua basalis contain cytotrophoblast and multinucleate trophoblast giant cells derived from the mononuclear cytotrophoblastic population, which infiltrate the decidua basalis during the first 18 weeks of pregnancy. These cells penetrate as far as the inner one-third of the myometrium, but can often be observed at or near the decidual–myometrial junction. They are not found in the decidua parietalis or the adjacent myometrium, from which it may be inferred that the placental-bed giant cell represents a differentiative end stage in the extravillous trophoblast lineage. The striae of fibrinoid are irregularly interconnected and variable in prominence. Strands pass from Nitabuch's stria into the adjacent decidua which contains basal remnants of the endometrial glands and large and small decidual cells scattered in a connective tissue framework that supports an extensive venous plexus.

From the third month onwards the basal plate develops placental or cotyledonary septa, which are ingrowths of the cytotrophoblast covered with syncytium that grow toward but do not fuse with the chorionic plate (Fig. 9.4). The septa circumscribe the maternal surface of the placenta into 15–30 lobes, often termed cotyledons. Each cotyledon surrounds a limited portion of the intervillous space associated with a villous trunk from the chorionic plate. From the fourth month these septa are supported by tissue from the decidua basalis. Throughout the second half of pregnancy the basal plate becomes thinned and progressively modified: there is a relative diminution of the decidual elements, increasing deposition of fibrinoid, and admixture of fetal and maternal derivatives.

**Intervillous space**

The intervillous space contains the main trunks of the villous stems and their arborizations into intermediate and terminal villi (Figs 9.4 and 9.5). A villous trunk and its branches may be regarded as the essential structural, functional and growth unit of the developing placenta.

At term, from the inner myometrium to the intervillous space, the walls of most spiral arteries consist of fibrinoid matrix within which cytotrophoblast is embedded. This arrangement allows expansion of the arterial diameter (and so slows the rate of arterial inflow and reduces the perfusion pressure) independent of the local action of vasoconstrictive agents. Endothelial cells, where present, are often hypertrophic. The veins that drain the blood away from the intervillous space pierce the basal plate and join tributaries of the uterine veins. The presence of a marginal venous sinus, which hitherto has been described as a constant feature occupying the peripheral margin of the placenta and communicating freely with the intervillous space, has not been confirmed.

Recent anatomic and in vivo studies have shown that human placentation is in fact not truly haemochorial in early pregnancy (Jauniaux et al 2003). From the time of implantation, the extravillous trophoblast not only invades the uterine tissues but also forms a continuous shell at the level of the decidua. The cells of this shell not only
anchor the placenta to the maternal tissue but also form plugs in the tips of the utero-
placental arteries (Burton et al 1999). The shell and the plugs act like a labyrinthine
interface that filters maternal blood, permitting a slow seepage of plasma but no true
blood flow into the intervillous space. This is supplemented by secretions from the
uterine glands, which are discharged into the intervillous space until at least 10 weeks
(Burton et al 2002). The comparison of these anatomical features with physiological
data obtained in utero reveals that the architecture of the human first trimester
gestational sac is designed to limit fetal exposure to oxygen to that which is strictly
necessary for its development. This creates a physiological placental hypoxia which
may protect the developing embryo against the deleterious and teratogenic effects of
oxygen, and also a uterine O\textsubscript{2} gradient which exerts a regulatory effect on placental
tissue development and function. In particular it influences cytotrophoblast
proliferation and differentiation along the invasive pathway and villous vasculogenesis.

At the end of the first trimester the trophoblastic plugs are progressively dislocated,
allowing maternal blood to flow progressively more freely and continuously within
the intervillous space. During the transitional phase of 10–14 weeks gestation, two-thirds
of the primitive placenta disappears, the chorionic cavity is obliterated by the growth
of the amniotic sac, and maternal blood flows progressively throughout the entire
placenta (Jauniaux et al 2003). These events bring the maternal blood closer to the
fetal tissues, facilitating nutrient and gaseous exchange between the maternal and
fetal circulations.

**Structure of a placental villus**

Chorionic villi are the essential structures involved in exchanges between mother and
fetus. The villous tissues separating fetal and maternal blood are therefore of crucial
functional importance. From the chorionic plate, progressive branching occurs into the
villous tree, as stem villi give way to intermediate and terminal villi. Each villus has a
core of connective tissue containing collagen types I, III, V and VI, as well as
fibronectin. Cross-banded fibres (30–35 nm) of type I collagen often occur in bundles,
whereas type III collagen is present as thinner (10–15 nm) beaded fibres, which form
a meshwork that often encases the larger fibres. Collagens V and VI are present as
6–10 nm fibres closely associated with collagens I and III. Laminin and collagen type
IV are present in the stroma associated with the basal laminae that surround fetal
vessels and also in the trophoblast basal lamina. Overlying this matrix are
ensheathing cyto- and syncytiotrophoblast cells bathed by the maternal blood in the
intervillous space (Figs 9.4, 9.5 and 9.6). Cohesion between the cells of the
cyotrophoblast and also between the cytotrophoblast and the syncytium is provided
by numerous desmosomes between the apposed plasma membranes.
In earlier stages, the cytotrophoblast forms an almost continuous layer on the basal lamina. After the fourth month it gradually expends itself producing syncytium, which comes to lie on the basal lamina over an increasingly large area (80% at term), and becomes progressively thinner. Cytotrophoblastic cells persist until term, but because the increase in villous surface area outstrips their proliferation they are usually disposed singly. In the first and second trimester cytotrophoblastic sprouts, covered in syncytium, are present and represent a stage in the development of new villi. Cytotrophoblast columns at the tips of anchoring villi extend from the villous basal lamina to the maternal decidual stroma.

The cells of the villous cytotrophoblast (Langhans cells) are pale-staining with a slight basophilia. Ultrastructurally, they have a rather electron-translucent cytoplasm, and relatively few organelles. They contain intermediate filaments, particularly in association with desmosomes. Between the desmosomes, the membranes of adjacent cells are separated by approximately 20 nm. Sometimes the intercellular gap widens to accommodate microvillous projections from the cell surfaces, and it occasionally contains patches of fibrinoid. A smaller population of intermediate cytotrophoblast may also be found in the chorionic villi. This postmitotic population represents a state of partial differentiation between the cytotrophoblast stem cell and the overlying syncytium.

The syncytium is an intensely active tissue layer across which most transplacental transport must occur. It is a selectively permeable barrier that allows water, oxygen and other nutritive substances and hormones to pass from mother to fetus, and some of the products of excretion to pass from fetus to mother. It secretes a range of placental hormones into the maternal circulation. Syncytial cytoplasm is more strongly basophilic than that of the cytotrophoblastic cells and is packed with organelles consistent with its secretory phenotype. Where the plasma membrane adjoins basal lamina it is often infolded into the cytoplasm, whereas the surface bordering the intervillous space is set with numerous long microvilli, which constitute the brush border seen by light microscopy.
Glycogen is thought to be present in both layers of the trophoblast at all stages, although it is not always possible to demonstrate its presence histochemically. Lipid droplets occur in both layers and are free in the core of the villus. In the trophoblast they are found principally within the cytoplasm, but they also occur in the extracellular space between cytotrophoblast and syncytium, and between the individual cells of the cytotrophoblast. The droplets diminish in number with advancing age and may represent fat in transit from mother to fetus, and/or a pool of precursors for steroid synthesis. Membrane-bound granular bodies of moderate electron density occur in the cytoplasm, particularly in the syncytium, some of which are probably secretion granules. Other membrane-bound bodies, lysosomes and phagosomes, are involved in the degradation of materials engulfed from the intervillous space.

In the immature placenta, syncytial sprouts represent the first stages in the development of new terminal villi, which later become invaded by cytotrophoblast and villous mesenchyme. Occasionally, adjacent syncytial sprouts make contact and fuse to form slender syncytial bridges. The sprouts may become detached, forming maternal syncytial emboli, which pass to the lungs. It has been computed that some 100,000 sprouts pass daily into the maternal circulation. In the lungs they provoke little local reaction and apparently disappear by lysis. However, they may occasionally form foci for neoplastic growth. Syncytial sprouts are present in the term placenta, but are usually degenerating.

Syncytial knots are aggregates of degenerating nuclei, and may represent a sequestration phenomenon by which senescent nuclear material is removed from adjacent metabolically active areas of syncytium. Fibrinoid deposits are frequently found on the villous surface in areas lacking syncytiotrophoblast. They may constitute a repair mechanism in which the fibrinoid forms a wound surface that is subsequently re-epithelialized by trophoblast. The extracellular matrix glycoprotein tenasin has been localized in the stroma adjacent to these sites.

The core of a villus contains small and large reticulum cells, fibroblasts, and macrophages (Hofbauer cells). Early mesenchymal cells probably differentiate into small reticulum cells, which in turn produce fibroblasts or large reticulum cells. The small reticulum cells appear to delimit a collagen-free stromal channel system through which Hofbauer cells migrate. Mesenchymal collagen increases from a network of fine fibres in early mesenchymal villi to a densely fibrous stroma within stem villi in the second and third trimester. After approximately 14 weeks, the stromal channels found in immature intermediate villi are infilled by collagen to give the fibrous stroma characteristic of the stem villus.

Fetal vessels include arterioles and capillaries. Pericytes may be found in close association with the capillary endothelium, and from late first trimester the vessels are surrounded externally by a basal lamina. From the second trimester (and a little later in terminal villi), dilated thin-walled capillaries are found immediately adjacent to the villous trophoblast, their respective basal laminae apparently fuse to produce a vasculo-syncytial interface.

Transport across placental villi

The mechanism of transfer of substances across the placental barrier (membrane) is complex. The volume of maternal blood circulating through the intervillous space has
been assessed at 500 ml per minute. Simple diffusion suffices to explain gaseous exchange. Transfer of ions and other water-soluble solutes is by paracellular and transcellular diffusion and transport: the relative importance of each of these for most individual solutes is unknown, and the paracellular pathway is morphologically undefined. Glucose transfer involves facilitated diffusion, while active transport mechanisms carry calcium and at least some amino acids. The fat-soluble and water-soluble vitamins are likely to pass the placental barrier with different degrees of facility. The water-soluble vitamins B and C pass readily. Water is interchanged between fetus and mother (in both directions) at approximately 3.5 litres per hour. The transfer of substances of high molecular weight, such as complex sugars, some lipids and hormonal and non-hormonal proteins, varies greatly in rate and degree, and is not so well understood: energy-dependent selective transport mechanisms including receptor-mediated transcytosis are likely to be involved.

Lipids may be transported unchanged through and between the cells of the trophoblast to the core of the villus. The passage of maternal antibodies (immunoglobulins) across the placental barrier confers some degree of passive immunity on the fetus: it is widely accepted that transfer is by micropinocytosis. Investigation of transplacental mechanisms is complicated by the fact that the trophoblast itself is the site of synthesis and storage of certain substances, e.g. glycogen.

The placenta is an important endocrine organ. Some steroid hormones, various oestrogens, β-endorphins, progesterone, hCG and human chorionic somatomammotropin (hCS), which is also known as placental lactogen (hPL), are synthesized and secreted by the syncytiotrophoblast. The trophoblast also contains enzyme systems that are associated with the synthesis of steroid hormones.

It has been suggested that leukocytes may migrate from the maternal blood through the placental barrier into the fetal capillaries. It has also been shown that some fetal and maternal red blood cells may cross the barrier. The former may have important consequences, e.g. in Rh incompatibility.

The majority of drugs are small molecules and are sufficiently lipophilic to pass the placental barrier. Many are tolerated by the fetus, but some may exert grave teratogenic effects on the developing embryo (e.g. thalidomide). A well-documented association exists between maternal alcohol ingestion and fetal abnormalities. Addiction of the fetus can occur to substances of maternal abuse such as cocaine and heroin.

A wide variety of bacteria, spirochaetes, protozoa and viruses, including human immunodeficiency virus (HIV), are known to pass the placental barrier from mother to fetus, although the mechanism of transfer is uncertain. The presence of maternal rubella in the early months of pregnancy is of especial importance in relation to the production of congenital anomalies.
FETAL MEMBRANES

The implanting conceptus consists initially of three cavities and their surrounding epithelia. The original blastocyst cavity, surrounded by trophoblast, is now termed the chorionic cavity (synonymous with extraembryonic coelom). It is a large cavity containing the much smaller amniotic cavity and secondary yolk sac (see Fig. 9.1). The apposition of the latter two cavities delineates the extent of the early embryo. The chorionic cavity becomes lined with extraembryonic mesoblast which is also reflected over the outer surface of the amnion and yolk sac. A fourth cavity, the allantois, develops later as a caudal hypoblastic diverticulum that becomes embedded within the extraembryonic mesenchyme, forming the connecting stalk of the embryo. It does not have a direct mesothelial covering.

Chorion

The chorion consists of developing trophoblast and extraembryonic mesothelium. It varies in thickness during development both temporally and spatially. It is thickest at the implantation site throughout gestation as the chorion frondosum and then the placenta, and thinner as gestation progresses over the remainder of its surface as the chorion laevae (Fig. 9.3). At term the chorion consists of an inner cellular layer containing fibroblasts and a reticular layer of fibroblasts and Hofbauer cells, which resembles the mesenchyme of an intermediate villus. The outer layer consists of cytotrophoblast 3 to 10 cells deep, resting on a pseudo-basement membrane, which extends beneath and between the cells. Occasional obliterated villi within the trophoblast layer are the remnants of villi present in the chorion frondosum of the first trimester. Although the interface between the trophoblast and decidua parietalis is uneven, no trophoblast infiltration of the decidua parietalis occurs.

Yolk sac

As the secondary yolk sac forms it delineates a cavity lined with parietal, and perhaps visceral, hypoblast, which is continuous with the developing endoderm from the primitive streak (Ch. 10). The secondary yolk sac is the first structure that can be detected ultrasonographically within the chorionic cavity (Jauniaux et al 1991). Its diameter increases slightly between 6 and 10 weeks of gestation, reaching a maximum of 6–7 mm after which its size decreases.

The inner cells of the yolk sac (denoted endoderm in many studies, although this layer is restricted to the embryo itself) display a few short microvilli and are linked by juxtaluminal tight junctions (Jones & Jauniaux 1995). Their cytoplasm contains numerous mitochondria, whorls of rough endoplasmic reticulum, Golgi bodies and secretory droplets, giving them the appearance
of being highly active synthetic cells. With further development the epithelium becomes folded to form a series of cyst-like structures or tubules, only some of which communicate with the central cavity. The cells synthesize several serum proteins in common with the fetal liver, such as alpha-fetoprotein (AFP), alpha-1-antitrypsin, albumin, pre-albumin and transferrin (Jauniaux & Gulbis 2000). With rare exceptions, the secretion of most of these proteins is confined to the embryonic compartments.

The yolk sac becomes coated with extraembryonic mesenchyme, which forms mesenchymal and mesothelial layers. A diffuse capillary plexus develops between the mesothelial layer and the underlying secondary yolk sac wall, and subsequently drains through vitelline veins to the developing liver. The mesothelial layer bears a dense covering of microvilli: the presence of numerous coated pits and pinocytotic vesicles gives it the appearance of an absorptive epithelium (Jones & Jauniaux 1995).

The secondary yolk sac plays a major role in the early embryonic development of all mammals. In laboratory rodents it has been demonstrated as one of the initial sites of haematopoiesis. Recent human data indicate that it has an absorptive role for molecules of maternal and placental origin found in the chorionic cavity (Gulbis et al 1998) and mediates the main movement of molecules passing from the chorionic cavity to the yolk sac and subsequently to the embryonic gut and circulation.

After week 9 the cellular components of the wall of the secondary yolk sac start to degenerate, and their function is subsumed into exchanges at the placental chorionic plate. With embryonic development of the midgut, the connection of the yolk sac to the embryo becomes attenuated to a slender and elongated vitelline intestinal duct. Both the yolk sac and its duct remain within the extraembryonic coelom (chorionic cavity) throughout gestation, located between the amnion and chorion as they fuse, near the placental attachment of the umbilical cord.

**Allantois**

The allantoenteric diverticulum (see Fig. 10.1) arises early in the third week as a solid, endodermal outgrowth from the dorsocaudal part of the yolk sac into the mesenchyme of the connecting stalk. It soon becomes canalized. When the hindgut is developed, the proximal (enteric) part of the diverticulum is incorporated in its ventral wall. The distal (allantoic) part remains as the allantoic duct and is carried ventrally to open into the ventral aspect of the cloaca or terminal part of the hindgut (Fig. 9.7A). The allantois is a site of angiogenesis, giving rise to the umbilical vessels which connect to the placental circulation. The extraembryonic mesenchyme around the allantois forms the connecting stalk, which is later incorporated into the umbilical cord.
In the fetus, the allantoic duct, which is confined to the proximal end of the umbilical cord, elongates and thins. However, it may persist as an interrupted series of epithelial strands at term, in which case the proximal strand is often continuous at the umbilicus with the median intra-abdominal urachus, and
this in turn continues into the apex of the bladder.

Amnion (chorio-amnion)

The original amniotic cells develop from the edges of the epiblast of the embryonic disc which ultimately form the interface with the skin at the umbilical region. Between the 10th and 12th weeks of pregnancy the amniotic cavity expands until it makes contact with the chorion to form the chorio-amnion, an avascular membrane which persists to term. The amniotic membrane extends along the connecting stalk and forms the outer covering of the umbilical cord. After birth, the site of this embryonic/extraembryonic junction is important, because the extraembryonic cell lines will die, causing the umbilical cord to degenerate and detach from the body wall. In cases of anomalous development of the ventral body wall, e.g. gastroschisis and exomphalos, the reflections of the amnion along the forming umbilical cord may be incomplete (see below).

The inner surface of the amnion consists of a simple cuboidal epithelium. It has a microvillous apical surface beneath which is a cortical web of intermediate filaments and microfilaments. There are no tight junctional complexes between adjacent cells and cationic dyes penetrate between the cells as far as the basal lamina. The intercellular clefts present scattered desmosomes, but elsewhere the clefts widen and contain interlacing microvilli. These features are consistent with selective permeability properties. The epithelium synthesizes and deposits extracellular matrix into the compact layer of acellular stroma located beneath the basal lamina, as well as the basal lamina itself.

Towards the end of gestation increasing numbers of amniotic cells undergo apoptosis. Apoptotic cells become detached from the amnion and are found in the amniotic cavity at term. The highest incidence is in weeks 40–41, independent of the onset of labour. Apoptosis may play a role in the fragility and rupture of the fetal membranes at term.

Human amniotic epithelial cells are thought to be pluripotent because they arise so early from the conceptus. They can be distinguished from the epiblast cells from day 8. Amniotic cells lack the major histocompatibility complex antigen and so the amnion can be exposed to the maternal immune system without eliciting a maternal immune response. Cultured human amniotic epithelial cells express a range of neural and glial markers, including glial fibrillary acidic protein, myelin basic protein, vimentin and neurofilament proteins, suggesting that these cells may supply neurotrophic factors to the amniotic fluid. They also appear to have a hepatocyte gene expression profile, showing albumin production, glycogen storage and albumin secretion in culture. In organ culture they have been shown to secrete 30-fold larger amounts of albumin than in monolayer culture, and to secrete alpha-1-
antitrypsin (Takashima et al 2004). Amnion is used in the repair of corneas after trauma and as a graft material for reconstructing vaginas in women with cloacal abnormalities.
AMNIOTIC FLUID

The amniotic fluid, or liquor amnii, is derived from multiple sources throughout gestation. These include secretions from amniotic epithelium, filtration of fluid from maternal vessels via the parietal decidua and amniochorion, filtration from the fetal vessels via the chorionic plate or the umbilical cord, and fetal urine and fetal lung secretions. In early pregnancy, diffusion from intracorporeal vessels via fetal skin provides another source. Once the gut is formed, fetal swallowing of amniotic fluid is a normal occurrence: the fluid is absorbed into the fetal circulation and passes via the placental barrier into the maternal circulation. There is rapid exchange between the amniotic fluid and maternal and fetal circulations via the placenta and fetal kidneys.

In the early stages amniotic fluid resembles blood plasma in composition and is probably formed largely by transport across the amniotic membrane. As pregnancy advances, it becomes progressively more dilute, partly by the addition of fetal urine. It contains less than 2% of solids, including urea, inorganic salts, a small amount of protein and frequently a trace of sugar. Glycoprotein secretions from amniotic epithelium include fibronectin. Secretory products of the maternal decidua, including prolactin and insulin-like growth factor binding protein 1 (IGF-BP1), are present in the liquor. There is experimental evidence of a considerable and rapid flux of water across the amniotic membrane.

The amount of amniotic fluid increases in quantity up to the sixth or seventh month and then diminishes slightly. At the end of pregnancy it is usually somewhat less than a litre. It provides a buoyant medium which supports the delicate tissues of the young embryo and allows free movement of the fetus during the later stages of pregnancy. It also diminishes the risk to the fetus of injury from without.

A volume of amniotic fluid in excess of 2 litres is generally considered to be abnormal and constitutes polyhydramnios. A deficiency is termed oligohydramnios and absent amniotic fluid is anhydramnios. (For information about amniotic fluid volume and ranges in gestation consult Brace & Wolf 1989.) Oligohydramnios in the second or third trimester is usually the result of premature rupture of the membranes, uteroplacental insufficiency or urinary tract malformations, e.g. bilateral renal agenesis or obstruction of the lower urinary tract. The major concern with oligohydramnios at less than 20 weeks is the significant risk of pulmonary hypoplasia and neonatal death. The mechanism for the development of pulmonary hypoplasia is poorly understood but loss of lung fluid, and chest compression are contributing factors. Conversely, increased amniotic fluid volume (polyhydramnios) is found essentially in two major circumstances: reduced fetal swallowing or absorption of amniotic fluid and increased fetal urination. Reduced fetal
swallowing may be due to congenital malformations e.g. anencephaly, upper intestinal tract obstruction (oesophageal atresia), compressive pulmonary disorders (congenital diaphragmatic hernia) and neuromuscular impairment of swallowing. The cause for abnormal amniotic fluid volume can often be elucidated with detailed prenatal ultrasound examination.
UMBILICAL CORD

The formation of the connecting stalk is described in Chapter 10, and the early formation of the umbilical cord is described on p. 1209. The umbilical cord ultimately consists of an outer covering of flattened amniotic epithelial cells and an interior mass of mesenchyme of diverse origins (Fig. 9.7). It contains two tubes of hypoblastic origin, the vitelline-intestinal and allantoic ducts, and their associated vitelline and allantoic (umbilical) blood vessels. The yolk stalk and continuing duct extend the length of the cord whereas the allantoic duct extends only into its proximal part.

The mesenchymal core is derived from the somatopleuric extraembryonic mesenchyme covering the amniotic folds, splanchnopleuric extraembryonic mesenchyme of the yolk stalk (which carries the vitelline vessels and clothes the yolk duct), and similar allantoic mesenchyme of the connecting stalk (which clothes the allantoic duct and initially carries two umbilical arteries and two umbilical veins). These various mesenchymal compartments fuse and are gradually transformed into the loose connective tissue (Wharton's jelly) that characterizes the more mature cord. The tissue consists of widely spaced elongated fibroblasts separated by a delicate three-dimensional meshwork of fine collagen fibres, which contains a variety of hydrated glycosaminoglycans, and is particularly rich in hyaluronic acid.

The vitelline and allantoic (umbilical) vessels, which are initially symmetrical, become modified as a result of changes in the circulation. The vitelline vessels involute, whereas most of the allantoic (umbilical) vessels persist. The right umbilical vein disappears but the two umbilical arteries normally remain. Occasionally one umbilical artery may disappear; there is some correlation within structural anomalies, most often cardiac, in such cases. The vessels of the umbilical cord are rarely straight, and are usually twisted into either a right- or left-handed cylindrical helix. The number of turns involved ranges from a few to over 300. This conformation may be produced by unequal growth of the vessels, or by torsional forces imposed by fetal movements. Its functional significance is obscure: perhaps the pulsations and contractions of the helical vessels assist the venous return to the fetus in the umbilical vein.

Anomalies of the fetal anterior abdominal wall such as exomphalos and gastroschisis may affect the arrangement of the outer covering of amnion cells along the proximal end of the umbilical cord. Exomphalos arises from a failure of the lateral folds along the ventral surface of the embryo resulting in failure of the normal embryonic regression of the mid-gut from the umbilical stalk into the abdominal cavity. The abdominal contents, including intestines and liver or spleen covered by a sac of parietal peritoneum and amnion, are herniated into the base of the umbilical cord. In gastroschisis, the insertion of the umbilical cord is intact and there is evisceration of the intestine through a
small abdominal wall defect usually located to the right of the umbilical cord: this results in free loops of bowel in the amniotic cavity. Theories concerning the aetiology of this defect include abnormal involution of the right umbilical vein or disruption of the omphalo-mesenteric artery by ischaemia.

Mature umbilical vessels, particularly the arteries, have a strong muscular coat which contracts readily in response to mechanical stimuli. The outermost bundles pursue an interlacing spiral course, and when they contract they produce shortening of the vessel and thickening of the media, with folding of the interna and considerable narrowing of the lumen. This action may account for the periodic sharp constrictions of contour, the so-called valves of Hoboken, which often characterize these vessels.

The fully developed umbilical cord is on average some 50 cm long and 1–2 cm in diameter. Its length varies from 20–120 cm: exceptionally short or long cords are associated with fetal problems and complications during labour. A long umbilical cord may prolapse through the cervix into the vagina once the fetal membranes rupture and this may be exacerbated by conditions that prevent the fetal head from fully occupying the maternal pelvis e.g. pelvic tumours (fibroids), ovarian cysts, placenta praevia and prematurity. Compression of the cord by the presenting part of the fetus, or an umbilical artery spasm will lead to fetal hypoxia and death if untreated. The risk of perinatal death rises as the interval from diagnosis to delivery increases. The treatment is either funic replacement (pushing the cord back above the fetal head) or more commonly immediate caesarean section, depending on factors such as the fetal viability.

The distal end of the umbilical cord usually attaches in the central portion of the placenta, but in a minority of cases velamentous insertion is observed (i.e. into the membranes) and this may be associated with vulnerability to injury and fetal haemorrhage. This is especially important if the placenta is low lying and may be associated with vasa praevia in which case fetal blood vessels run across the internal os. Inadvertent rupture of the fetal vessels in spontaneous labour or at the time of amniotomy (artificial rupture of membranes to induce labour) will cause fetal haemorrhage and may prove fatal (see placental variations).
REFERENCES

At stage 6 the conceptus is composed of the walls of three cavities: the large chorionic cavity is surrounded by a meshwork of trophoblast and developing villi and lined with extraembryonic mesoblast. The chorion, trophoblast and extraembryonic mesoblast enclose the extraembryonic coelom and contain the much smaller amniotic cavity and yolk sac (see Fig. 9.1). These latter cavities abut at the embryonic bilaminar disc where the epithelial epiblast and visceral hypoblast are approximated. A fourth cavity, the allantois, will form as a hypoblastic diverticulum in stage 7. The ‘bilaminar disc’ commonly referred to in embryology texts does not yet possess the definitive layers of embryonic ectoderm and endoderm that will give rise to embryonic structures. Only the epiblast will give rise to the embryo; all other layers produced so far are extraembryonic. The amnion and chorion (and surrounding mesoblast) are part of the extraembryonic somatopleure, whereas the yolk sac, allantois and surrounding extraembryonic mesoblast constitute extraembryonic splanchnopleure. At the junctional zone surrounding the margins of the embryonic area, where the walls of the amnion and yolk sac converge, the somatopleuric and splanchnopleuric layers of extraembryonic mesoblast are continuous.

The terms epiblast and hypoblast are used to make the distinction between the earliest bilaminar disc layers and the later embryonic layers. Epiblast and hypoblast contain mixed populations of cells with little restriction (see p. 193), which establish the placental structures and extraembryonic tissues before the production of embryonic cell lines at gastrulation. The older terminology depicting three germ layers that give rise to the skin, gut lining and intervening tissues is thus incorrect for the bilaminar and trilaminar embryonic disc. The application and the retention of this aged terminology for the early stages of embryology continues to cause confusion and inhibits the development of more pertinent descriptive language to describe these early events.

At early stage 6, the epiblast is producing extraembryonic mesenchyme from its caudal margin. With the appearance of the primitive streak, a process is begun whereby cells of the epiblast either pass deep to the epiblast layer to form the populations of cells within the embryo, or remain on the dorsal aspect of the embryo to become the embryonic ectoderm. Although human embryos do not form a ‘gastrula’ as such, the term gastrulation is used here to denote an early period of development during which significant rearrangements, migrations and folding of the early embryo occur. The primitive streak is the site of organizer cells analogous to those found in embryos which do undergo gastrulation. The appearance of the primitive streak therefore marks the beginning of a period when gross alterations in morphology and complex rearrangements of cell populations occur. During this time, the epiblast will give rise to a complex multilaminar structure with a defined craniocaudal axis. By the end of gastrulation, cell populations from different, often widely separated, regions of the embryonic disc will become spatially related and the embryonic shape will have been produced.

Primitive streak and node

Seen from the dorsal (epiblastic) aspect, at stage 6, the embryonic disc appears
The primitive streak is first seen in the caudal region of the embryonic disc at this stage as a collection of pluripotent cells, orientated along its long axis in the median position, conferring the future craniocaudal axis of the embryo (Figs 10.1 and 10.2). Although the future cranial and caudal regions of the embryo are well within the boundaries of the embryonic disc, it has become the practice to term the region of the disc closest to the streak ‘caudal’, and the region of the disc furthest from the streak ‘cranial’ or ‘rostral’. With the development of the streak, the terms medial and lateral can be used. The relative dimensions of the primitive streak and the fates of the cells that pass through it change with the developmental stage. Thus the streak extends half way along the disc in the stage 6 embryo, reaches its greatest relative length in stage 7 and its maximum length in stage 8.
Fig. 10.1 Longitudinal section through an early conceptus. Ingression of mesoblast is occurring at the primitive streak and the notochord is ingressing via the primitive (Hensen’s) node.
Formation of the primitive streak is induced by the underlying visceral hypoblast which remains beneath the streak even at later stages. The primitive streak may be considered to be generally homologous with the blastopore of lower vertebrates (e.g. amphibia), with the nodal region corresponding to the dorsal lip. Experiments clearly show the lip of the blastopore to be a dynamic wave front on which cells are carried into the interior to form the roof of the archenteron, a situation analogous to ingression through the node of the prechordal plate and endoderm. The primitive streak similarly may be considered analogous to the coapted, or fused, lateral lips of the blastopore, and the cloacal membrane and its immediate environs are considered analogous to the ventral lip of the blastopore.

At the primitive streak, epiblast cells undergo a period of intense proliferation, the rate of division being much faster than that of blastomeres during cleavage. Streak formation is associated with the local production of several cell layers, extensive disruption of the basal lamina, increase in adhesive plaques and gap junctions, synthesis of vimentin, and loss of cytokeratins by the emerging cells.

As the epiblast cells proliferate, two ridges are formed on each side of the primitive streak, which appears to sink between them. The lower midline portion of the streak is termed the primitive groove. The process by which cells become part of the streak and then migrate away from it beneath the epiblast is termed ingression.

The primitive node, or Hensen’s node, is the most rostral region of the primitive streak. It appears as a curved ridge of cells similar in shape to the top of an old fashioned keyhole. Cells ingressing from the ridge pass into the primitive pit (the most rostral part of the primitive groove), and then migrate rostrally beneath the epiblast. The primitive node has been recorded in all stage 7 human embryos: it produces axial cell populations, the prechordal plate, notochord, embryonic endoderm and the medial halves of the somites. Experimental removal of the node results in complete absence of the notochord and a failure of neurulation.

**Position and time of ingression through the primitive streak**

Studies of cell fate have shown that epiblast cells that will pass through the streak are randomly located within the epiblast layer before their ingression, and that epiblast fate is determined at or before the time of ingression through the streak, indicating that passage through the primitive streak is the most important factor for future differentiation.

The position and time of ingression through either streak or node directly affect the developmental fate of cells. Passage through the streak is specified according to position, e.g. via the node, or rostral, middle or caudal regions of the streak. Cells that
ingress through the primitive node give rise to the axial cell lines, the prechordal mesenchyme and notochord, and to the endoderm and the medial halves of the somites. The rostral portion of the primitive streak produces cells for the lateral halves of the somites, whereas the middle streak produces the lateral plate mesoblast. The adjacent caudal portion of the streak gives rise to the primordial germ cells, which can be distinguished histologically and histochemically, and the most caudal portion of the streak contributes cells to the extraembryonic mesoblast until the somites are visible. A composite of the information on the position of ingressation through the streak and node is shown in Fig. 10.3. The epiblast cells that do not pass through the streak but remain instead within the epiblast population give rise to the neural and surface ectoderm of the embryo.

Fig. 10.3 The predictive fates of the epiblast cell population at the time the primitive streak is present.

Prechordal plate

The earliest cells migrating through the primitive node and streak give rise to both the embryonic endoderm and the notochord. The prechordal plate is first seen at stage 7. It has been defined as a localized thickening of the endoderm rostral to the notochordal process, although it is seen as a highly developed mesenchymal mass in contact with the floor of the neural groove, rostral to the notochordal process, rather than as an epithelial layer. The prechordal plate is a temporary collection of cells
which underlies the neural plate during stage 9. It is composed of cells that are similar to, or larger and more spherical than, the ingressing endodermal cells (Müller & O'Rahilly 2003). In stage 8 embryos the prechordal plate is up to eight cells deep and extends along the long axis of the embryonic disc. By stages 9 and 10 the cells at the lateral edge of the plate have begun to migrate laterally as free mesenchymal cells and the plate reduces in height to two cells deep. At stage 11 the migrating prechordal mesenchyme forms bilateral premandibular mesenchymal condensations and is no longer a median structure. The extent of prechordal cells remaining within the endoderm is not clear.

**Notochord**

The notochord, also called chordamesoderm, the head process or chorda, arises from epiblast cells of the medial part of the primitive node. It passes through several stages during development. The cells of the early notochordal process express myogenic markers transitorily as they migrate beneath the epiblast, but later they become epithelial, forming junctions and a basal lamina. The notochordal cells are intimately mixed with endodermal cells, as both cells lines ingress at the same time (Figs 10.1, 10.2 and 10.4). In the stage 8 embryo, the ingressing notochordal cells remain in the midline along the cephalocaudal axis. They form a rostral part, which is composed of a cell mass continuous with the prechordal mesenchyme, a mid portion in which cells are arranged in a tube with a central notochordal canal, and a caudal epithelial layer of cells, the notochordal plate, which is contiguous with the embryonic endoderm and forms a roof to the secondary yolk sac. There is a transitory opening between the primitive node (and amniotic cavity) and the secondary yolk sac called the neurenteric canal (so named because its upper opening is in the future caudal floor of the neural groove, and its lower opening is into the archenteron, which is the primitive gut); it may still be found at stage 9, and the site of the neurenteric canal can be recognized in stage 10 embryos. The ingression of notochordal cells at the primitive node is matched by specification of the overlying neural ectodermal cells, and the notochordal plate is thus matched in length by the future neural floor plate. Both the notochord and the region of the floor plate of the neural tube may arise from a common progenitor cell. The early notochord is important for the maintenance and subsequent development of the neural floor plate and the induction of motor neurones. Removal of the notochord results in elimination of the neural floor plate and motor neurones, and expression of sensory cells types.
Caudal eminence

From stages 9 and 10 the region between the neurenteric canal and the cloacal membrane (see below), including the primitive streak, is termed the caudal eminence. It consists of the caudal region of the trunk composed of mesenchyme derived from the primitive streak and epiblast, covered with surface ectoderm. Whereas ingressing of cells through the primitive streak gives rise to the prechordal and notochordal plates, and cells rostral to the neurenteric canal (see below), the cells of the caudal eminence arise from local division of a mesenchymal population positioned caudal to the neurenteric canal. The caudal portions of the notochord, which form later in development when secondary neurulation processes begin, arise from these cell...
populations, sometimes termed the caudoneural hinge or junction (see p. 361). This tissue is thicker and more advanced in differentiation than the tissues derived from the early primitive streak.

**Embryonic endoderm**

Before ingression, definitive embryonic endoderm cells are found in the epiblast located at the primitive node and rostral primitive streak. In the mouse, the endodermal cells lie beneath the epiblast mainly in the midline, interspersed with presumptive notochordal cells, forming the roof of the secondary yolk sac. The ingressing endoderm displaces the visceral hypoblast into the secondary yolk sac wall by a dramatic territorial expansion that is brought about by a change in the morphology of the cells (Figs 10.1, 10.2 and 10.4). The putative endoderm cells are cuboidal epithelial cells within the node, but they become squamous in the endoderm layer; this could result in a four-fold increase in the surface area covered by the cells. A complete replacement of the visceral hypoblast has not yet been confirmed, and there may be a mixed population of cells in the endodermal layer in the early stages. Ingression of cells through the streak and node in the human is apparent at stage 6, and by stage 7 a population of endoderm and notochord cells is present beneath the epiblast (Figs 10.1, 10.2 and 10.4). During stages 6–11, the midline roof of the secondary yolk sac becomes populated mainly by the notochordal plate, which remains in direct lateral continuity with the endodermal cells. It is not until stage 11, after the definitive notochord is formed, that the endoderm cells can join across the midline. For the developmental fate of the embryonic endoderm, see Fig. 12.3.

**Intraembryonic mesoblast (mesenchyme)**

Epiblast cells ingress through the cranial and middle parts of the streak individually, maintaining their apical epithelial contacts while elongating ventrally. The cells become flask-shaped, with thin attenuated apical necks and broad basal regions. The basal and lateral surfaces form lamellipodia and filopodia and the apical contact is released. The cells are now free mesoblast cells, their fibroblastic, stellate morphology reflecting the release from the epithelial layer. Once through the streak, the cells migrate away from it, using the basal lamina of the overlying epiblast and extracellular matrix as a substratum. The cells contact one another by filopodia and lamellipodia, with which they also contact the basal lamina. Gap junctions have been observed between filopodia and cell bodies. With the appearance of the mesoblast, spaces form between the epiblast and visceral hypoblast that are filled with extracellular matrix rich in glycosaminoglycans. The migrating mesoblast has a leading edge of cells that open up the migration routes, and the following cells seem to be pulled along behind in a coordinated mass movement. Mesoblast formed by cells migrating through the primitive node and rostral primitive streak will form the paraxial mesenchyme, whereas cells migrating through the middle to caudal streak will form the lateral plate mesenchyme (Figs 10.1, 10.2; see Fig. 10.6).
Embryonic ectoderm

When the ingestion of cells through the primitive streak is completed, the epithelial cells remaining in the epiblast layer are termed embryonic ectoderm cells. This layer still contains a mixed population, because both surface ectoderm cells and neural ectoderm cells are present. It is believed that these cells were originally in the cranial half of the disc when the primitive streak first appeared, at which time the neural-fated cells were closest to the streak, and the surface ectoderm cells were most cranial (Fig. 10.3). The process of primary neurulation relocates most of the neuroepithelial cells
Primordial germ cells

Although early studies on human embryos have reported primordial germ cells, and described their development from the early endoderm of the yolk sac and allantois, it is now clear from animal experimentation that the primordial germ cells arise from epiblast ingressing at the caudal end of the primitive streak (Fig. 10.3). It is not known whether these cells originate from rostral regions that migrate to the streak, or from local caudal regions. Extremely early segregation of the germ cells, when the epiblast layer consists of only 10–13 cells, has been demonstrated. It has been suggested that the primordial germ cells remain sequestered in the extraembryonic mesenchyme at the caudal end of the embryo until the embryonic endoderm has been produced and gastrulation completed, and that they start to migrate along the allantoic and hindgut endoderm as the folding of the embryo begins. The formation of the tail fold brings the proximal portion of the allantois within the body, so reducing the final distance over which the cells migrate to the genital ridges. Further development of the germ cells is described on page 1318.
TRILAMINAR DISC

Although the stage 8 embryo is termed a trilaminar disc, the concept of three epithelial layers forming a trilaminar disc is incorrect: the middle, mesoblast, layer is several cells thick with intervening extracellular matrix. The embryo at this stage, approximately 23 days after ovulation, is pear-shaped, and broader cranially than caudally (Fig. 10.5). The upper epiblast cells are tall, and form a pseudostratified columnar epithelial layer with a basal lamina, except at the primitive streak, where the cells are ingressing to form the other layers. The more centrally placed epiblast will give rise to neural ectoderm (neurectoderm) and the more laterally placed epiblast will give rise to surface ectoderm. The future neural ectoderm is seen as a neural plate which matches the length of the notochordal plate directly beneath, being slightly wider near the prechordal plate. The lower embryonic endoderm, a simple squamous layer with a developing basal lamina, is not always complete at this stage, particularly in the midline caudal to the prechordal plate, which is still occupied by the notochordal process or plate.
The middle, mesoblast, layer is composed of free cells migrating cranially, laterally and caudally from the primitive streak (Fig. 10.4). They produce extracellular matrix, which separates the epiblast and endoderm of the embryonic area and permits their passage. The streams of mesoblast extend between the epiblast and endoderm over all of the disc area except cranially at the buccopharyngeal membrane (where the endoderm and ectoderm become apposed once the prechordal mesenchyme has migrated laterally), and caudally at the cloacal membrane (a patch of thickened endoderm, similar to the buccopharyngeal membrane, caudal to the primitive streak). The mesoblast on each side of the notochord is termed paraxial mesenchyme.

Mesoblast that passes in a cranial direction flanks the notochordal plate and passes around the prechordal plate region, converging medially to fuse in the midline beyond its cephalic border. This transmedian mass, in which the heart and pericardium will develop, is initially termed the cardiogenic mesoblast. It fuses with the junctional zone of extraembryonic mesoblast around the extreme cephalic margin of the embryonic area. This region will eventually form the septum transversum and primitive ventral mesentery of the foregut. Mesoblast passing laterally from the streak soon approaches and becomes confluent with the extraembryonic mesoblast around the margins of the disc, i.e. at the junctional zone where the splanchnic and somatic strata of extraembryonic mesoblast merge. Mesoblast that streams caudally from the primitive streak skirts the margins of the cloacal membrane and then converges towards the caudal midline extremity of the embryonic disc to become continuous with the extraembryonic mesoblast of the connecting stalk. It is unclear if the lower layer of the cloacal membrane consists of visceral hypoblast, like the more cranial primitive streak (the hypoblast is necessary for maintaining the streak), or if it is replaced by
migrating embryonic endoderm, or if there is a region for ingestion of endoderm at the caudal end of the streak, similar to the node cranially.

Still further caudally, the embryonic disc develops a midline diverticulum adjacent to the cloacal membrane. This diverticulum, the allantois, projects into the extraembryonic connecting stalk (Fig. 10.4, see also Fig. 10.6 and p. 180). There is little information about which cells form the allantois, i.e. whether it is composed of visceral hypoblast, parietal hypoblast or embryonic endoderm. The allantois later develops a rich anastomotic blood supply around it, in the manner of the yolk sac.

The generation of cells at the primitive node produces midline endoderm, notochord and the floor plate of the future neural tube. As the notochord grows and elongates, there is a matched growth of neural floor plate cells until both cell lines extend to the buccopharyngeal membrane. The epiblast lateral to the midline contains both future surface and neural ectoderm. The latter becomes arranged between the primitive node and buccopharyngeal membrane: cells destined to be in the neural plate lie medially, and those destined for the neural crest lie laterally (Fig. 10.5). A smaller subpopulation of neuronal cells, the ectodermal placodes, are arranged either close to the neural crest or within the rostral limit of the neural plate itself.
FOLDING OF THE EMBRYO

In a diagrammatic representation of the trilaminar disc prior to folding and viewed from the ectodermal aspect, all of the future external surface of the body is delimited (see Fig. 10.5). The ends of the gut tube are specified on the ectodermal surface at the buccopharyngeal and cloacal membranes, which are regions where the ectoderm and underlying endoderm are apposed without intervening mesoblast. In the midline between these membranes, proliferation of the neural ectoderm matches the underlying migration of mesoblast from the primitive streak, so that the neural plate covers the paraxial mesenchyme on each side of the notochord (Fig. 10.6E). As the paraxial mesenchyme segments (see p. 763), the formation of the epithelial somites elevates the edges of the neural plate and initiates primary neurulation (Figs 10.6F and 10.8). The neural plate itself undergoes concurrent morphological changes. The most medial cells become wedge-shaped, forming the neural groove. Further elevation of the edges of the neural groove permits fusion of the neuronal populations in the dorsal midline to form the neural tube. The surface ectoderm forms the putative dorsal epidermis (Figs 10.6G and 10.8). Cells at the lateral edge of the neural plate termed neural crest cells remain as a linearly arranged mesenchymal population between these two epithelia. Fusion of the neural tube begins in the future rhombencephalic region of the embryo and proceeds rostrally and caudally to about the level of somite 29. Neurulation is described further in Chapter 24. A population of neural epithelial cells remain within the surface ectoderm; at this stage they are termed ectodermal placodes.
Fig. 10.8 A human embryo at stage 10, 2.1 mm long, with nine somites: right lateral and dorsal aspects. Nearly all the yolk sac and the caudal amnion have been excised.
Fig. 10.7 Scanning electron micrographs of rat embryos at the time of neurulation. A. Ventral view, showing the neural fold (NF), and the heart (H) with the somatopleuric pericardial membrane and surface ectoderm removed; the arrow indicates the entrance to the foregut via the cranial intestinal portal. B. Dorsolateral view; the arrows indicate the extent of rostral (to the right) and caudal (to the left) neural tube formation.

(Photographs by P Collins; printed by S Cox, Electron Microscopy Unit, Southampton General Hospital.)

The representation of a person on the trilaminar disc (Fig. 10.9) shows, to some extent, the way in which the positions of the main body structures are already specified in the unfolded embryo. The portion of ectoderm lateral to the neural plate and the paraxial mesenchyme will form structures within the back.
The portion of the disc between the buccopharyngeal membrane and the edge of the disc will become the ventral thoracic wall and the ventral abdominal wall cranial to the umbilicus. Further caudally, midway along the neural axis, the lateral portions of the disc will become the lateral and ventral abdominal walls of the trunk. The portion of the disc beyond the cloacal membrane will form the ventral abdominal wall caudal to the umbilicus. The circumference of the disc, where the embryonic tissue meets the extraembryonic membranes, will become restricted to the connection between the ventral abdominal wall and the umbilical cord, i.e. the umbilicus.
the pericardial coelom. The limbs, although represented in this diagram, are not present on the disc at this stage. The usefulness of this diagram lies in its illustration of the extent of the anterior body wall both rostral to the buccopharyngeal membrane and caudal to the cloacal membrane. The future dorsal regions of the body are found medially on the disc, while the ventral regions of the body are situated laterally and peripherally on the disc. After head and tail folding and lateral folding, the peripheral edge of the disc becomes constricted as the edge of the umbilicus.

Head folding begins at stage 9, when the fusing cranial neural plate rises above the surface ectoderm and the portion of the disc rostral to the buccopharyngeal membrane (which contains the cardiogenic mesenchyme) moves to lie ventral to the developing brain (Fig. 10.6). The prosencephalon and buccopharyngeal membrane are now the most rostral structures of the embryo. The previously flat region of endoderm, which may contain cells from the prechordal plate, is now modified into a deep tube, the primitive foregut. Tail folding can be seen in stage 10 embryos, when the entire embryo comes to rise above the level of the yolk sac. Similar movement of the part of the disc caudal to the cloacal membrane results in its repositioning ventral to the neural plate. Generally, as the embryo rises above the edges of the disc, the lateral regions of the disc are drawn ventrally and medially, contributing to the lateral folding of the embryo.
FORMATION OF THE INTRAEMBRYONIC COELOM

At and just before stage 9 (before formation of the head fold), vesicles appear between the mesenchymal cells cranial to the buccopharyngeal membrane and within the cranial lateral plate mesenchyme. At the periphery of the vesicles, the mesenchymal cells develop junctional complexes and apical polarity, and form an epithelium. The vesicles become confluent to form a horse-shoe shaped tube, the intraembryonic coelom, which extends caudally to the level of the first somite and laterally into the lateral plate mesenchyme towards the extraembryonic mesenchyme. The intra- and extra-embryonic coeloms do not communicate at this stage. The lateral plate mesenchyme thus develops somatopleuric coelomic epithelium subjacent to the ectoderm, and a splanchnopleuric coelomic epithelium next to the embryonic endoderm (Fig. 10.4; see also Fig. 12.2C(iv)).

During development of the head fold, the morphological movements that organize the foregut and buccopharyngeal membrane have a similarly profound effect on the shape of the intraembryonic coelom. The midline portion of the originally flat, horse shoe-shaped coelom moves ventrally, leaving the caudal arms of the horse shoe in their original position. In this way the midline part of the coelom, which was originally just rostral to the buccopharyngeal membrane, comes to lie ventral to the foregut (caudal to the buccopharyngeal membrane), and the two lateral extensions of the coelom pass close to the lateral walls of the foregut on each side. The caudal portions of the coelom (the two arms of the horse shoe), which in the unfolded disc communicated laterally with the extraembryonic coelom, turn 90° to lie lateral to the gut, and communicate with the extraembryonic coelom ventrally.

Compartments of the coelom that will later in development give rise to the body cavities can already be seen. The midline ventral portion, caudal to the buccopharyngeal membrane, becomes the pericardial cavity. The canals lateral to the foregut (pericardioperitoneal canals) become the pleural cavities and the uppermost part of the peritoneal cavity. The remaining portion of the coelom becomes the peritoneal cavity. By stage 11, the intraembryonic coelom within the lateral plate mesenchyme extends caudally to the level of the caudal wall of the yolk sac. The intra- and extra-embryonic coeloms communicate widely on each side of the midgut along the length of the embryo from the level of the 4th somite (Fig. 10.10; see also Fig. 12.1).
In the early embryo, the intraembryonic coelom provides a route for the circulation of coelomic fluid and, with the beating of the heart tube, functions as a primitive circulation that takes nutritive fluid deep into the embryo, until it is superseded by the blood vascular system. The coelomic channel, and the primitive circulation that passes through it, is of paramount importance up to stage 13. Whereas the superficial tissues of the embryo can receive nutrients via the amniotic sac and yolk sac fluids, the deeper tissues are, until the formation of the coelom, under conditions similar to those found in tissue culture. From stage 10, however, exocoelomic fluid, propelled by the first contractions of the developing heart, is brought into contact with the deeply placed mesenchyme. This early ‘circulation’ ensures that an adequate supply of nutrients reaches the rapidly increasing amount of embryonic tissue, and meets most of the requirements of the deeper mesenchymal derivatives. From stage 12 the endothelial system expands and fills rapidly with plasma, which passes across the locally thinned coelomic epithelium into the large hepatocardiac channels that project into the pericardio-peritoneal canals at the level of the seventh somite.

In spite of the importance of the coelom in defining the body cavities, and of the coelomic epithelium in the production of the major mesenchymal populations of the trunk (see Fig. 12.2), only a few workers have considered the overall contribution of the coelom and its epithelium to the embryo (Streeter 1942, Langemeijer 1976). The coelom can be described as a single, tubular organ which is comparable to the neural tube, in that it possesses a specialized wall that encloses a cavity. Certainly, the
proliferating coelomic epithelium has many similarities to the neural ectoderm. It is pseudostratified columnar epithelium with an inner germinal layer from which cellular progeny migrate. After the germinal phase, both epithelia ultimately form the lining of a cavity, i.e. ependyma for the neural epithelium, and mesothelium for the coelomic epithelium. The coelomic epithelium, like the neural epithelium, produces cells destined for different fates from different sites and at different developmental times. Coelomic cells are like the neural epithelium, in that they have apical epithelial specializations and tapering basal processes that are in direct contact with the underlying mesenchyme, without an intervening basal lamina. The possibility of the tapering processes forming directional signals for migrating progeny, similar to radial glia of the neural tube, has not been examined.
EMBRYONIC CELL POPULATIONS AT GASTRULATION

After gastrulation, the cells of the embryo contribute to two fundamental types of tissue, namely epithelial and mesenchymal. Differentiation of specialized circulating blood cells and other cell types occurs in sequence. Embryonic and fetal cell types are replaced later in development or after birth.

Epithelia

Epithelial populations in the embryo have many of the morphological characteristics of differentiated epithelia, i.e. they are composed of sheets of closely packed cells, with narrow intercellular clefts containing minimal extracellular material, and a developed basal lamina containing specific proteins synthesized by the epithelium itself. The cells usually show juxtaluminal lateral surface specializations such as desmosomes, tight junctions, gap junctions, etc., and specializations of the apical surface, such as microvilli or cilia. Characteristically, epithelia clothe internal and external surfaces as simple or compound cellular sheets that separate phases of differing composition (e.g. the external environment and the subepithelial tissue fluids; intravascular and extravascular fluids, etc.). Traffic of materials in the intercellular clefts is limited. Traffic occurs across the cells because their limiting membranes, which function as energy-dependent selective barriers, enhance the passage of some materials and impede the passage of others.

Embryonic epithelia differ from those in the fetus and adult. Two distinct types can be identified. Early germinal epithelia which give rise to epithelial or mesenchymal populations of the embryo and confer their early patterning are termed organizers, e.g. the primitive streak. Later germinal epithelia give rise to system-specific progenitor populations, e.g. the ventricular zone of the neural tube. All epithelia other than special germinal epithelia divide to produce embryonic growth throughout development and may retain stem cells which will divide throughout life.

Mesenchyme

The terms mesoblast and mesenchyme are used in this text in a specific manner and not interchangeably. Previously, cells forming a population between the epiblast and hypoblast were termed mesoderm and, more recently, mesenchyme. The terms primary and secondary mesenchyme have been used to distinguish between those cells which arise from ingression through the primitive streak and those which arise from neural crest ingression respectively. Primary mesenchymal cells revert to epithelia at their destinations. However, whereas some primary mesenchymal cells may become epithelial within a short time frame, e.g. somites and lateral plate, other cells may transform later, e.g. the epithelium lining blood vessels. To
cope with these conflicts in terminology, the mixed population of epiblast cells that ingress through the primitive streak and come to lie between the epiblast and embryonic endoderm is termed mesoblast until the cells have migrated to their final position, at which time the populations of mesenchyme can be identified and their fates inferred.

Mesoblastic and mesenchymal cells have no polarity. They form junctional complexes, which are not exclusively juxtaluminal, and they produce extracellular matrix molecules and fibres from the entire cell surface. Mesenchymal populations are formed from a range of germinal epithelia and by proliferation of mesenchymal cells directly, and occupy all the regions between the various epithelial layers described above. The term mesoderm is reserved for the coelomic epithelia that later form mesothelia.

Mesenchymal cells support epithelia throughout the developing body, both locally where they contribute to the basement membrane and form the lamina propria and smooth muscle of tubes, and generally where they differentiate into connective tissue. Specific mesenchymal populations control the patterning of local regions of epithelium (e.g. the zone of polarizing activity on the postaxial limb border posterior to the apical ectodermal ridge).

**Extracellular matrix**

The space beneath epithelia and between mesenchyme cells is filled with extracellular matrix: both epithelial and mesenchymal cells synthesize extracellular matrix molecules and their receptors. Epithelial cells produce a two-dimensional basal lamina, which contains a variety of matrix molecules including laminin, fibronectin, type IV collagen and various proteoglycans. The particular molecules can vary during development according to spatial and temporal patterns, resulting in changes in the behaviour of the underlying mesenchymal cells (e.g. in patterning of the basal regions of the skull). Mesenchymal cells produce extracellular matrix molecules in three dimensions. Those adjacent to an epithelial layer will connect with its basal lamina, forming a basement membrane that secures the epithelial layer to the underlying tissue. Cells deep within a mesenchymal population may synthesize matrix molecules (fibrillar or granular) to separate cells locally, open up migration routes or leave information within the matrix to act on cell populations passing at a later time.

Molecules of the extracellular matrix are complex: they include more than 19 individual types of collagen (some of which are capable of being individually spliced to give more than 100 variants), proteoglycans and glycoproteins (which come in a wide variety of forms, with and without binding proteins), and elastic fibres. Hyaluronic acid, a glycosaminoglycan, has a vast capacity to bind water molecules and so create and structure the space between the mesenchymal cells, thereby producing much of the overall shape of an
embryo. Experimental removal of hyaluronic acid prevents the formation of cell migration routes, removes the support for overlying epithelia, and disrupts the normal branching of glandular systems.

Fibronectin deposited extracellularly along a migration pathway will affect cells that touch it later, causing realignment of their intracellular actin filaments and thus of their orientation; it also induces cell migration. The receptors for extracellular matrix molecules such as fibronectin and laminin were originally termed integrins because they integrate extracellular proteins and intracellular cytoskeletal elements (via $\alpha$ and $\beta$ subunits that span the cell membrane), allowing them to act together: the binding preference of integrins depends upon their combination of subunits and environmental conditions.

The extracellular matrix is structured rather than random. Epithelial and mesenchymal cell populations can structure the space around them by secretion of particular matrix molecules or growth factors, which in turn can organize the cells that contact them. Cell–matrix interactions and matrix–cell interactions control the position of migration routes and cellular ‘decisions’ to migrate or to begin to differentiate. Matrix molecules propagate developmental instructions from cell to cell and form a far-reaching four-dimensional (spatial and temporal) mechanism of communication.

**Transition between epithelial and mesenchyme states**

Transformations of cell morphology from epithelium to mesenchyme, and *vice versa*, occur in specific places and times during development, and can be seen as ways of dispersing germinal centres with increasing restriction. The first epithelial-to-mesenchyme transition occurs at the primitive streak, a germinal epithelium which confers embryonic specification on the resultant mesoblast population. The mesoblast so formed migrates and the cells undergo mesenchyme-to-epithelial transitions when they reach their final destinations. Series of small epithelial germinal centres, the somites, are formed, as are larger, more extensive, germinal epithelial sheets which line the walls of the intraembryonic coelom. The coelomic walls, especially those derived from somatopleure and splanchnopleure, form germinal epithelia which give rise to the major mesenchymal populations that form the viscera. The early epithelial somites undergo further local epithelial-to-mesenchyme transitions to form the sclerotomes, and subsequently form several germinal epithelia in the epithelial plate of each somite. Later mesenchyme-to-epithelium transitions are not associated with the formation of germinal epithelia: the most common involve the transition of mesenchyme into the endothelium of the vascular system (see p. 1017). The nephrons of the mesonephric and metanephric systems also form from mesenchyme-to-epithelial transition (see p. 1308).

CHAPTER 11 – Embryonic induction and cell division

EMBRYONIC INDUCTION AND CELL DIVISION

Cell populations within the embryo interact to provide the developmental integration and fine control necessary to achieve tissue-specific morphogenesis. In the early embryo, such interactions may occur only if particular regions of the embryo are present, e.g. signalling centres or organizers. As the embryo matures, some interactions tend to occur between adjacent cell populations, e.g. epithelium and mesenchyme, and later between adjacent differentiating tissues, e.g. between nerves and muscle, or between muscle and skeletal elements. The interactions between adjacent epithelia and underlying connective tissue continue throughout embryonic and fetal life and extend into postnatal life. In the adult, these interactions also permit the metaplastic changes that tissues can undergo in response to local environmental conditions.

Tissue interactions result in changes or reorganization of one or both tissues, which would not have occurred in the absence of the tissue interactions. The process of tissue interaction is also called induction, i.e. one tissue is said to induce another. The ability of a tissue to respond to inductive signals is called competence, and denotes the ability of a cell population to develop in response to the environments present in the embryo at that particular stage. After a cell population has been induced to develop along a certain pathway, it will lose competence and become restricted. Once restricted, cells are set on a particular pathway of development; after a number of binary choices (further restrictions) they are said to be determined. Determined cells are programmed to follow a process of development that will lead to differentiation. The determined state is a heritable characteristic of cells, and is the final step in restriction. Once a cell has become determined, it will progress to a differentiated phenotype if the environmental factors are suitable.

The process of determination and differentiation within embryonic cell populations is reflected by the ability of these populations to produce specific proteins. Primary proteins (colloquially termed housekeeping proteins) are considered essential for cellular metabolism, whereas proteins synthesized as cells become determined, those specific to the state of determination, are termed secondary proteins; for example, liver and kidney cells, but not muscle cells, produce arginase. Fully differentiated cells produce tertiary proteins, which no other cell line can synthesize, e.g. haemoglobin in erythrocytes.

As populations of cells become progressively determined, they can be described within a hierarchy of cellular development as transiently amplifying cells, progenitor cells, stem cells and terminally differentiated cells.

Transiently amplifying cells

Transiently amplifying cells undergo proliferative cell mitosis and produce cells that are equally determined. At some stage, and as a result of an inductive stimulus, these cells will enter a quantal cycle that culminates in a quantal mitosis. This will result in an increase in the restriction of their progeny, which continue to undergo proliferative mitoses at a progressive level of determination. The quantal mitosis corresponds to the time of binary choice when the commitment of the progeny is different from that of
Progenitor cells

Progenitor cells are already determined along a particular pathway. They may individually follow that differentiation pathway, or may proliferate and produce large numbers of similarly determined progenitor cells that subsequently differentiate; neuroblasts or myoblasts are examples of progenitor cells.

Stem cells

Either individually or as a population, stem cells can both produce determined progeny and reproduce themselves. It is generally believed that stem cells undergo asymmetric divisions, in which one daughter cell remains as a stem cell, while the other proceeds along a differentiation pathway; in marked contrast, proliferative cell division may be symmetrical, producing derived cells with an identical determination. Human embryonic stem cells (hESC) are pluripotent cells that can be derived from the inner cell mass of human blastocysts *in vitro*; or obtained surplus to *in vitro* fertilization fertility programmes; or created from oocytes donated and fertilized for that purpose. Although not yet achieved, it is hoped that hESCs can be coaxed down particular pathways under appropriate pharmaceutical conditions to produce differentiated cells that will be effective in reversing some degenerative diseases (e.g. dopamine producing neurones for Parkinson's disease, insulin producing islet cells for diabetes), or to replace acutely damaged tissues (e.g. motor neurones for acute spinal cord injury; cardiomyocytes in acute myocardial infarction). Proof of principle has been demonstrated in some animal models, and multipotent haematopoietic progenitor stem cells from human umbilical cord blood are now used as an alternative treatment to bone marrow transplantation for the treatment of some inherited genetic disorders (thalassaemia) and blood malignancies (leukaemias).

Terminally differentiated cells

By virtue of their extreme specialization, terminally differentiated cells can no longer divide, e.g. erythrocytes and neurones. Apoptosis is a particular variety of terminal differentiation in which the final outcome is the death of the individual cells or cell populations. It occurs in the developing limb, where cells die along the pre- and postaxial limits of the apical ectodermal ridge, limiting its extent, and also between the digits, permitting their separation.

Tissue interactions

There are two types of cell and tissue interaction, namely, permissive and instructive.

In a permissive interaction, a signal from an apposing tissue is necessary for the successful self-differentiation of the responding tissue. This means that a particular cell population (or the matrix molecules secreted by the cells that it contains) will maintain mitotic activity in an adjacent cell population. Since a variety of different cell populations may permit a specific cell population to undergo mitosis and cell differentiation, no specific instruction or signal which may limit the developmental options of the responding tissue is involved: this signal therefore does not influence the developmental pathway selected and there is no restriction. The responding tissue has the intrinsic capacity to develop, and only needs appropriate environmental
conditions in order to express this capacity. Permissive interactions often occur later in development, when a tissue whose fate has already been determined is maintained and stabilized by another.

An instructive (directive) interaction (induction) changes the cell type of the responding tissue, so that the cell population becomes restricted. Wessells (1977) proposed four general principles in most instructive interactions:

1. In the presence of tissue A, responding tissue B develops in a certain way.
2. In the absence of tissue A, responding tissue B does not develop in that way.
3. In the absence of tissue A, but in the presence of tissue C, tissue B does not develop in that way.
4. In the presence of tissue A, a tissue D, which would normally develop differently, is changed to develop like tissue B.

Principles 1–4 are exemplified during induction of the lens vesicle by the optic cup (p. 699). An example of principle 4 is the experimental association of chicken flank ectoderm with mouse mammary mesenchyme, which results in the morphogenesis of mammary gland-like structures: chickens do not normally develop mammary glands.

Tissue interactions continue into adult life and are probably responsible for maintaining the functional heterogeneity of adult tissues and organs. This is exemplified by the complex tissue heterogeneity, with sharply compartmentalized boundaries, that occurs in the oral cavity. The junctions between the mucosa of the vestibule and the lip, and between the vermilion border and the facial skin, are distinct boundaries of specific epithelial and mesenchymal differentiation, and are almost certainly maintained by continuing epithelial–mesenchymal interactions in adult life. Perturbation of these interactions throughout the body may underlie a wide variety of adult diseases, including susceptibility to cancer and proliferative disorders.

**Signalling between embryonic cells and tissues**

Cellular interactions may be signalled by four principal mechanisms: direct cell–cell contact; cell adhesion molecules and their receptors; extracellular matrix molecules and their receptors; growth factors and their receptors. Many of these mechanisms interact, and it is likely that combinations of them are involved in development. Figure 11.1 illustrates diagrammatically some ways by which mesenchymal cells could signal to epithelial cells. An additional set of identical mechanisms could operate for epithelial-to-mesenchymal cell signalling. Clearly, the complexity of these mechanisms will increase in reciprocal interactions; moreover, a single molecule may have different effects on epithelial and mesenchymal cells.
The many ways by which mesenchyme cells could signal to epithelial cells. Precisely the same mechanisms can operate in reverse, i.e. epithelium to mesenchyme.

Fig. 11.1: The many ways by which mesenchyme cells could signal to epithelial cells. Precisely the same mechanisms can operate in reverse, i.e. epithelium to mesenchyme.

Direct cell–cell contact permits the construction of gap junctions, which are important for communication and the transfer of information between cells. The transient production of gap junctions is seen as epithelial somites are formed, between neuroepithelial cells within rhombomeres, and in the tunica media of the outflow tract of the heart. Endogenous electrical fields are also believed to have a role in cell–cell communication. Such fields have been demonstrated in a range of amphibian embryos, and in vertebrate embryos during primitive streak ingression. Neuroepithelial cells are electrically coupled, regardless of their position relative to interrhombomeric boundaries.

The spatial and temporal distribution of a variety of cell adhesion molecules has been localized in the early embryo. The appearance of these molecules correlates with a variety of morphogenetic events that involve cell aggregation or disaggregation, for example, an early response of groups of cells to embryonic inductive influences is the expression of cadherins, calcium-dependent adhesion molecules typically found in epithelial populations. Other molecules found in the extracellular matrix, e.g. fibronectin and laminin, can modulate cell adhesion by their degree of glycosylation. Self-assembly or cross-linking by matrix molecules may affect cell adhesiveness by increasing the availability of binding sites or by obscuring them.

Extracellular matrix molecules include localized molecules of the basal lamina, e.g. laminin, fibronectin, and much larger complex associations of collagen, glycosaminoglycans, proteoglycans and glycoproteins between the mesenchyme cells. Mutations of the genes that code for extracellular matrix molecules give rise to a number of congenital disorders, e.g. mutations in type I collagen produce osteogenesis imperfecta; mutations in type II collagen produce disorders of cartilage; mutations in fibrillin are associated with Marfan’s syndrome.

Growth factors are distinguished from extracellular matrix molecules. They can be delivered to, and act upon, cells in a variety of ways, namely endocrine, autocrine, paracrine, intracrine, juxtacrine and matricrine (Fig. 11.2). Many growth factors are...
secreted in a latent form, e.g. associated with a propeptide (latency-associated peptide) in the case of transforming growth factor β, or attached to a binding protein, in the case of insulin-like growth factors.

**Fig. 11.2** Cells can also communicate by the reception, production and secretion of growth factors. A typical embryonic mesenchyme cell could receive and produce growth factors in this way.

---

1. **Endocrine**  Delivery of growth factor by the bloodstream from a distant biosynthetic site to the target mesenchyme cell.

2. **Autocrine**  Synthesis of growth factor by the cell, its secretion, binding and activation of a surface receptor elsewhere on its own surface.

3. **Paracrine**  Synthesis of growth factor by the cell, its secretion and diffusion to an adjacent cell (or group of cells) where it binds to and activates a cell surface receptor.

4. **Juxtacrine**  Synthesis of growth factor by the cell. The growth factor remains on the cell surface and binds to and activates a receptor on an immediately adjacent cell.

5. **Intracrine**  Synthesis of growth factor within the cytoplasm of the cell. The growth factor moves to the nucleus and binds and activates its own nuclear receptors.

6. **Matricrine**  Synthesis and export of growth factor from the cell. The growth factor binds to the extracellular matrix where it remains active and subsequently binds to and activates a receptor for that growth factor on the same or a different cell.
MORPHOGENESIS AND PATTERN FORMATION

Morphogenesis may be described as the assumption of form by the whole, or part, of a developing embryo. As a term, it is used to denote the movement of cell populations and the changing shape of an embryo, particularly during early development.

The most obvious examples of morphogenesis are the large migrations that occur during gastrulation; local examples include branching morphogenesis, which occurs e.g. in the developing lungs and kidneys, and in most glandular organs. The development of branches from a tubular duct occur over a period of time. An interaction between the proliferating epithelium of the duct and its surrounding mesenchyme and extracellular matrix results in a series of clefts that produce a characteristic branching pattern (Fig. 11.3). During tubular and acinar development, hyaluronidase secreted by the underlying mesenchymal cells breaks down the basal lamina produced by the epithelial cells; this increases epithelial mitoses locally and results in an expanding acinus. Cleft formation is initiated by the mesenchyme, which produces collagen III fibrils within putative clefts. (If the collagen is removed, no clefts develop, whereas if excess collagen is not removed, supernumerary clefts appear.) The collagen acts to protect the basal lamina from the effects of the hyaluronidase, which means that the overlying epithelia have a locally reduced rate of mitosis. The region of rapid mitoses at the tip of the acinus is therefore split into two, and two branches develop from this point.

![Fig. 11.3](image)

**Fig. 11.3** Branching of a tubular duct may occur as a result of an interaction between the proliferating epithelium of the duct and its surrounding mesenchyme and extracellular matrix. Mesenchymal cells initiate cleft formation by producing collagen III fibrils locally within the development clefts and hyaluronidase over other parts of the epithelium. Collagen III prevents local degradation of the epithelial basal lamina by hyaluronidase and slows the rate of mitosis of the overlying epithelial cells. In regions where no collagen III is produced, hyaluronidase breaks down the epithelial basal lamina and locally increases epithelial mitoses, forming an expanded acinus.

Pattern formation concerns the processes whereby the individual members of a mass of cells, initially apparently homogeneous, follow a number of different avenues of differentiation which are precisely related to each other in an orderly manner in space and time. The patterns embraced by the term apply not only to regions of regular geometric order, e.g. the crystalline lens, but also to asymmetric structures such as the limb. For such a process to occur, individual cells must be informed of their position within the embryo, and utilize that information for appropriate differentiation. Patterning of regions is seen in: the progress zone and zone of polarizing activity within the limbs; the fates of the medial and lateral and later the cranial and caudal
halves of the somites; the neural crest mesenchyme within the pharyngeal arches. For details of patterning in vertebrate development, see Tickle (2003).

Hox genes in development

Two related themes have emerged from experimental studies of development. First, that the control of embryonic morphology has been highly conserved in evolution between vertebrates and invertebrates, and second, that this control involves families of genes coding for proteins that act as transcriptional regulators.

The fruit fly, Drosophila, possesses eight homeotic genes that specify the structures developing on each body segment. These genes have been identified in vertebrates, raising the possibility that they have similar functions in development. They are termed homeobox genes, abbreviated to Hox in the mouse and HOX in humans, and are found on four clusters known as A, B, C and D. Individual genes are numbered from 1 to 13: 1 is a cephalic gene and 13 is a more caudally placed gene.

Homeobox genes are believed to be responsible, at least in part, for the evolutionary origin of the embryonic body plan (Robert 2001). Experimental study of transgenic animals in which the homeobox genes have been knocked out provide some evidence of their function: however, because developmental processes permit significant recovery from insult, some of the outcomes cannot be directly interpreted as demonstrating the effect of such gene loss.

Experimental approaches to embryology

One of the most exciting techniques to provide information on cell movements and fates during development is the use of chimeric embryos. Small portions of an embryo are excised and replaced with similar portions of an embryo from a different species at the same stage and the resulting development is then studied. This technique has been particularly effective using chick and quail embryos, because the nucleolus is especially prominent in all quail cells, whereas it is not prominent in chick cells, which means that quail cells may be easily identified within a chick embryo after chimeric transplantation (Le Douarin 1969). The technique has also confirmed the reciprocity of tissue interaction between the embryonic species, a phenomenon that had previously been illustrated, for a limited period, in co-cultures of embryonic avian and mammalian tissues. Somite development and vertebral formation have been studied in mouse–chick chimeras (Fontaine-Pérus 2000). The production in vitro, of human-animal chimeric cell lines is providing new ways of studying cellular pathways, as is the introduction of human artificial chromosome vectors into animal cells to study their interaction.

CHAPTER 12 – Cell populations at the start of organogenesis

SPECIFICATION OF THE BODY AXES AND THE BODY PLAN

Embryos may be thought of as being constructed with three orthogonal spatial axes (cephalocaudal, dorsoventral and laterolateral), plus a temporal axis. In mammalian embryos, axes cannot be specified at very early stages: embryonic axes can be defined only after the early extraembryonic structures have been formed and the inner cell mass can be seen. The position of the future epiblast can be predicted in human embryos when the hollow blastocyst has formed. The inner cell mass becomes (seemingly) randomly located on the inside of the trophectoderm and forms a population of epiblast cells subjacent to the trophoblast. This region implants first. It is not known whether the trophectoderm in contact with the inner cell mass initiates implantation, so that the future dorsal surface of the embryo is closest to the disrupted maternal vessels at the implantation site, or whether the inner cell mass can travel around the inside of the trophoblast to gain a position subjacent to the implantation site once implantation has started.

Axes may be conferred on the whole embryonic disc, which is initially flat and mainly two-dimensional. However, their subsequent orientation in the folded three-dimensional embryo will be completely different. The dorsal structures of the folded embryo form from a circumscribed central ellipse of the early flat embryonic disc (see Fig. 10.5). Lateral and ventral structures form from the remainder of the disc, and the peripheral edge of the disc eventually becomes constricted at the umbilicus (see Figs 10.9 and 10.10). Although the appearance of part of the epiblast is taken to specify the dorsal surface of the embryo, the inner layer, i.e. the hypoblast, is not by default a ventral embryonic structure.

The primary, cephalocaudal, axis is conferred by the appearance of the primitive streak in the bilaminar disc. The primitive streak patterns cells during ingression, and so also specifies the dorsoventral axis which becomes apparent after embryonic folding. The position of ingression through the streak confers axial, medial or lateral characteristics on the forming mesenchyme cells. The axial and medial populations remain as dorsal structures in the folded embryo, and the surface ectoderm above them will exhibit dorsal characteristics. The lateral plate mesenchyme will assume lateral and ventral positions after embryonic folding, and the surface ectoderm above this population will gain ventral characteristics.

The third and last spatial axis is the bilateral, or laterolateral axis, which appears as a consequence of the development of the former two axes. Initially, the right and left halves of the embryonic body are bilaterally symmetric. Lateral projections, the upper and lower limbs, develop in two places on each side of the body wall (somatopleure).

With the last axis established, the temporal modification of the original embryonic axes can be seen. The segmental arrangement of the cephalocaudal axis is very obvious in the early embryo and is retained in many structures in adult life. Similarly, dorsal embryonic structures remain dorsal and undergo relatively little change. However, structures that were originally midline and ventral, especially those derived from splanchnopleuric mesenchyme, e.g. the cardiovascular system and the gut, are subject to extensive shifts, and change from a bilaterally symmetric arrangement to an entire body that is now chiral, i.e. has distinct left and right sides.
The development of all the body organs and systems, organogenesis, begins after the dramatic events of gastrulation, when the embryo has attained a recognizable body plan. In human embryos this corresponds to the end of stage 10 (Fig. 12.1). The head and tail folds are well formed, with enclosure of the foregut and hindgut (proenteron and metenteron), although the midgut (mesenteron) is only partly constricted from the yolk sac. The forebrain projection dominates the cranial end of the embryo, and the buccopharyngeal membrane and cardiac prominence are caudal and ventral to it. The cardiac prominence contains the transmedian pericardial cavity, which communicates dorsocaudally with right and left pericardioperitoneal canals. These pass dorsally to the transverse septum mesenchyme and open caudally into the extraembryonic coelom on each side of the midgut. The intraembryonic mesenchyme has begun to differentiate and the paraxial mesenchyme is being segmented into somites. Neural groove closure is progressing caudally, so that a neural tube is forming between the newly segmenting somites. Rostrally, the early brain regions, which have not yet fused, can be discerned. The neuroepithelium is separated from the dorsal aspect of the gut by the notochord. The earliest blood vessels have appeared, and a primitive tubular heart occupies the pericardium. The chorionic circulation is soon to be established, after which the embryo rapidly becomes completely dependent upon the maternal bloodstream for its requirements. The embryo is connected to the developing placenta by a mesenchymal connecting stalk in which the umbilical vessels develop, and which also contains the allantois, a hindgut diverticulum. The lateral body walls are still widely separated. The embryo has contact with three different vesicles: the amnion, which is in contact with the surface ectoderm; the yolk sac, which is in contact with the endoderm; and the chorionic cavity, containing the extraembryonic coelom, which is in contact with the intraembryonic coelomic lining (see Fig. 10.10).
The early body plan of the embryo is segmented. The boundaries between the segments are maintained by the differential expression of genes and proteins that restrict cell migration in these regions. Organogenetic processes either retain the segmental plan, e.g. spinal nerves, or replace it locally, e.g. the modifications of somatic intersegmental vessels by the development of longitudinal anastomoses. Abnormalities may result from improper specification of segments along the cephalocaudal axis and may fail to produce the appropriately modified segmental plan.

The degree to which vertebrate embryos are developmentally constrained at this period of development is controversial. Comparative studies on the timing at which specific embryonic structures appear, heterochrony, have shown that other embryonic species do not follow the same developmental sequence as humans (Richardson & Keuck 2002). Although some developmental mechanisms are highly conserved, e.g. the homeobox gene codes, others may have been dissociated and modified in different vertebrate species during evolution.

Organogenesis, the further development of body regions and organs that is described elsewhere in this book, starts from about stage 10 (approximately 28 days). Although it is both conventional and convenient to consider the further development of each body system on an individual basis, not only do all systems develop simultaneously, they also interact and modify each other as they develop. This necessary interdependence is supported by the evidence of experimental embryology and reinforced by the phenomena of growth anomalies, which cut across the artificial boundaries of systems in most instances. For these reasons, it is recommended that the development of an individual system or body region should be studied in relation to others, especially those most closely associated with it, whether spatiotemporally or causally.
EMBRYONIC CELL POPULATIONS AT THE START OF ORGANOGENESIS

The developmental processes operating in the embryo between stages 5 and 9 enabled the construction of the bi- and tri-laminar embryonic disc, the intraembryonic coelom and new proliferative epithelia. From the end of stage 10, a range of local epithelial and mesenchymal populations now interact to produce viscera and appendages. The inductive influences on these tissues and their repertoire of responses are very different from those seen at the onset of gastrulation. The range of tissues present at the start of organogenesis, when the body plan is clear, is given below and shown in Figs 12.1 and 12.2. For a summary of the fates of the embryonic cell populations, see Fig. 12.3.
**Fig. 12.2**  
A. Mesoblast populations within the early embryonic disc.  
B. Stage 11 embryo, showing the position of the intraembryonic coelom (contained by the walls coloured blue) and the positions of the sections (i)–(iv), which are shown in C.  
C. Transverse sections, arranged cranial to caudal, from a stage 11 embryo. The populations of mesenchyme and the sites of mesenchymal proliferation are indicated.
Epithelial populations in the embryo

**Surface ectoderm**

During embryogenesis, the surface ectoderm shows regional differences in thickness. Ectoderm over the dorsal region of the head and trunk is thin, as is the pericardial covering; this has been interpreted as a consequence of the expansion of this epithelium over structures that are enlarging rapidly as development proceeds. After the surface ectoderm has completed a number of early interactions it forms the periderm, which remains throughout fetal life and differentiates into epidermis.

**Ectodermal ring and ectodermal placodes**

---

**Fig. 12.3** Structures that will be derived from specific epithelial and mesenchymal populations in the early embryo. CNS, central nervous system.
The ectoderm on the head and lateral borders of the embryo shows a zone of epithelial thickening, the ectodermal ring, which can be discerned from stage 10 and is completed by stage 12. Rostrally it contains populations of neuroectoderm that remain in the ectoderm after primary neurulation that are termed ectodermal placodes: these placodes may be considered to be neuroepithelial cells that remain within the surface ectoderm until central nervous system development has progressed sufficiently for their inclusion into sensory epithelia and cranial nerve ganglia. The neuronal placodes may invaginate *in toto* to form a vesicle, or remain as a neuronal layer, or contribute individually to neuronal structures with cells of other origins. The midline ectodermal thickening, the adenohypophysial placode, invaginates as Rathke's pouch and forms a vesicle immediately rostral to the buccopharyngeal membrane. The ectodermal ring then passes bilaterally to encompass the olfactory and optic placodes, which give rise to the olfactory sensory epithelium and the lens of the eye respectively. It then overlies the pharyngeal arches where it gives rise to epibranchial placodes which remove themselves individually from the ectoderm at stage 10–11 and become associated with the neural crest cells within the cranial sensory ganglia supplying the arches. It also forms specializations of the ectoderm on the frontonasal, maxillary and mandibular processes which give rise to the tooth buds and the outer coating of the teeth. The paired otic placodes overlying the rhombencephalon at the lateral portion of the second pharyngeal arch invaginate to form the otic vesicles, which give rise to the membranous labyrinth of the ear. The ectodermal ring then passes over the occipital and cervicothoracic parts of the embryo, superficial to the four occipital somites and later to the occipito-cervical junction. Further caudally it is associated with the upper limb field, where it will give rise to the apical ectodermal ridge. O'Rahilly & Müller (1985) have called the portion of the ring between the upper and lower limbs the intermembral part. It overlies the underlying mesonephric duct and ridge. In stages 14 and 15, this portion of the ectodermal ring gives rise to the mammary line. Caudal to the lower limb field, in the unfolded embryo, the ring passes distal to the cloacal membrane. In the folded embryo, this region becomes superior to the cloacal membrane and corresponds to the ectoderm associated with the external genitalia, particularly the genital tubercle and urogenital swellings.

**Neural ectoderm**

The neuroepithelium at the time of primary neurulation is pseudostratified. It has a midline hinge region which, with concomitant wedging of the cells in the lateral wall of the neural groove, promotes neural tube formation. The processes of the neuroepithelium abut onto internal and external limiting membranes. This epithelium proliferates to form all the cell lines of the central nervous system and, via the production of neural crest, all the cell lines of the peripheral nervous system.

**Notochord**

During stage 10, the notochordal plate undergoes a process which is similar to, but a mirror image of, neurulation, and forms an epithelial tube from caudal to rostral, ending with the pharynx. The notochordal plate forms a deep groove, the vertical edges of the groove move medially and touch, and then the endodermal epithelium from each side fuses ventral to the notochord. The cells swell and develop an internal pressure (turgor) that confers rigidity on the notochord. The notochord is surrounded
by a basal lamina, which is initially referred to as a perinotochordal sheath, but this term is subsequently applied to mesenchymal populations that surround the notochord. After stage 11, the tubular notochord is in contact with the neural tube dorsally and the endoderm ventrally. It is not a proliferative epithelium, but it has inductive effects on the overlying neural tube and the adjacent somites, and later provides a focus for sclerotomal migration.

**Endoderm**

The craniocaudal progression of development means that the endoderm of the early stomodeum develops ahead of other portions of the endodermal epithelium. The development of the pharyngeal arches and pouches (see Ch. 35) is closely associated with the development of the neural ectoderm and proliferation of the neural crest. The respiratory diverticulum arises slightly later when the postpharyngeal gut may also be distinguished (see pages 1033 and 1203). The endoderm gives rise to the epithelial lining of the respiratory and gastrointestinal tracts, the biliary system (see p. 1207), and the bladder and urethra (see pages 1307, 1310).

**Coelomic epithelium**

The coelomic epithelium lines the intraembryonic coelom, which is subdivided into a midline pericardial cavity, two bilateral pericardioperitoneal canals, and the initially bilateral peritoneal cavities; the latter are continuous with the extraembryonic coelom. The coelomic epithelium is a germinal epithelium. It produces the myocardium (see p. 189) and connective tissue populations for the viscera (see p. 1033), and also gives rise to the supporting cells for the germ cells (see p. 1314), the epithelial lining of the urogenital tracts (see p. 1313) and the mesothelial lining of the pericardial, pleural (see p. 1013) and peritoneal cavities (see p. 1314).

The relative dispositions of the neural epithelium, endodermal and coelomic epithelia are shown in Fig. 12.1.

**Mesenchymal populations in the embryo**

In the stage 10 embryo, the major mesenchymal populations are in place. Mesoblast is still being generated at the primitive streak and moving into the presomitic mesenchymal population adjacent to the notochord. Some mesoblast is also contributing to the lateral regions of the embryo. The different mesenchymal populations within the embryo from stage 10 onwards are described below. The relative dispositions of the early mesenchymal populations are shown in Fig. 12.2.

**Axial mesenchyme**

The first epiblast cells to ingress through the primitive streak form the endoderm and notochord and initially occupy a midline position. The earliest population of endodermal cells rostral to the notochordal plate is termed the prechordal plate. The notochordal cells remain medially and the endodermal cells subsequently flatten and spread laterally. The population of cells that remain mesenchymal in contact with the floor of the neural groove, just rostral to the notochordal plate, is termed prechordal mesenchyme (Fig. 12.4). These axial mesenchyme cells are tightly packed, unlike the more lateral paraxial cells, but unlike the notochord, they are not contained in an extracellular sheath. They are displaced laterally at the time of head flexion and form
bilateral premandibular mesenchymal condensations. They become associated with the local paraxial mesenchyme. Orthotopic grafting has demonstrated that these cells leave the edges of the prechordal mesenchyme and migrate laterally into the periocular mesenchyme, where they give rise to all of the extrinsic ocular muscles (see p. 702).

Paraxial mesenchyme

Epiblast cells that migrate through the primitive node and rostral primitive streak during gastrulation form mesoblast cells which migrate to a position lateral to the notochord and beneath the developing neural plate. Cells that ingress through the primitive node form the medial part of this paraxial mesenchyme, and cells that
ingress through the rostral streak form the lateral part (see Fig. 10.3). The paraxial mesenchyme extends cranially from the primitive streak to the prechordal plate immediately rostral to the notochord. Before somite formation, this mesenchyme is also termed presomitic or unsegmented mesenchyme in mammals (analogous to the segmental plate in birds). Paraxial mesenchyme rostral to the otic vesicle was previously believed not to segment. However, the mesenchyme in this region shows concentric rings of cell bodies and processes that form paired, bilateral cylinders, termed somitomeres.

Caudal to the otic vesicle, the paraxial mesenchyme on each side of the rhombencephalon segments into somites as the neural folds elevate and neurulation begins: somites are therefore post-otic. During somitogenesis the mesenchyme cells show changes in shape, and in cell–cell adhesion, and become organized into epithelial somites. This process begins at the eighth somitomere, which is just caudal to the midpoint of the notochordal plate. Somite one is also termed the first occipital somite. Somites can be seen on each side of the fusing neural tube in the human embryo from stage 9. Development proceeds in a craniocaudal direction, thus unsegmented paraxial mesenchyme is a transient structure. It forms somites from its cranial end, whilst mesenchyme is added to its caudal end by the regressing primitive streak. Somites give rise to the base of the skull (see p. 610); the vertebral column and ribs (see p. 764); and the skeletal muscle of the body, including that in the limbs (see p. 899).

*Septum transversum*

Early mesenchyme that invaginates through the middle part of the primitive streak comes to lie rostral to the buccopharyngeal membrane, where the cells form the epithelial wall of the pericardial coelom. As this epithelium proliferates, the visceral pericardial wall gives rise to the myocardium. The parietal pericardial wall forms mesenchyme, initially termed precardiac, or cardiac, mesenchyme, which is able to induce proliferation of hepatic endodermal epithelium. With further proliferation, the precardiac mesenchyme forms a ventral mass caudal to the heart, the septum transversum, which separates the foregut endoderm from the pericardial coelom (Fig. 12.2). By stage 11 the septum transversum extends dorsally on each side of the developing gut, and becomes continuous with the mesenchymal populations that proliferate from the walls of the pericardioperitoneal canals. Cells of the septum transversum give rise to the sinusoids of the liver (see p. 1207), the central portions of the diaphragm (see p. 1014) and the epicardium (see p. 1026).

*Neural crest*

The neural crest is unique, it gives rise to neural populations in the head and trunk and also provides an extensive mesenchymal population in the head with attributes similar, in terms of patterning, to somatopleuric mesenchyme. Neural crest cells arise from cells that lie initially at the outermost edges of the neural plate, between the presumptive epidermis and the neural tube. The cells are committed to a neural crest lineage before the neural plate begins to fold. After neurulation, neural crest cells form a transient axial population and then disperse, in some cases migrating over considerable distances, to a variety of different developmental fates. Unlike mesoblast, which is produced from the primitive streak, none of the cells that arise from the neural crest become arranged as epithelia. As the development and fate of
head and trunk neural crest cells are very different, they will be considered separately.

**Trunk neural crest**

Trunk neural crest is formed as the neural tube closes cranio-caudally, which means that various stages of crest development can be found in the more caudal regions of an embryo. As the neural tube begins to fuse dorsally in the midline, the neural crest cells lose their epithelial characteristics and junctional connections and form a band of loosely arranged mesenchyme cells immediately dorsal to the neural tube and beneath the ectoderm. Initially, most of the crest cells lie with their long axes perpendicular to the long axis of the neural tube. Later, the cell population expands laterally and around the neural tube as a sheet. Trunk neural crest cells move from their position dorsal to the neural tube via three routes (see Fig. 24.11) dorsolaterally, to form dorsal root ganglia throughout the trunk; ventrally, to form sympathetic ganglia, enteric nerves and the suprarenal medulla; and rostrocaudally along the aorta, to form the preaortic ganglia. In a second migration route, crest cells pass dorsolaterally between the ectoderm and the epithelial plate of the somite into the somatopleure, where they eventually form melanocytes in the skin.

**Head neural crest**

Unlike its counterpart in the trunk, head neural crest migrates before the neural tube closes. Two populations of crest cells develop. Some cells retain a neuronal lineage and contribute to the somatic sensory and parasympathetic ganglia in the head and neck (see p. 364). Others produce extensive mesenchymal populations: the crest cell population arising from the head is larger than that found at any trunk level. Each brain region has its own crest population that migrates dorsolaterally around the sides of the neural tube to reach the ventral side of the head. Crest cells surround the prosencephalic and optic vesicles and occupy each of the pharyngeal arches (see Ch. 35). They provide mesenchyme cells which will produce the connective tissue in parts of the neuro- and viscero-crania. All cartilage, bone, ligament, tendon, dermal components and glandular stroma in the head are derived from the head neural crest. Head neural crest also contributes to the tunica media of the aortic arch arteries.

**Lateral plate**

Lateral plate is the term for the early unsegmented mesoblast population lateral to the paraxial mesenchyme. Mesoblastic cells, which arise from the middle of the primitive streak (primary mesenchyme), migrate cranially, laterally and caudally to reach their destinations, where they revert to epithelium and form a continuous layer that adheres to the ectoderm dorsally and the endoderm ventrally. The epithelium faces a new intraembryonic cavity, the intraembryonic coelom, which becomes confluent with the extraembryonic coelom and provides a route for the circulation of coelomic fluid through the embryo. Once formed, the intraembryonic coelomic wall becomes a proliferative epithelium which produces new populations of mesenchymal cells. The mesenchymal population subjacent to the ectoderm is termed somatopleuric mesenchyme, and is produced by the somatopleuric coelomic epithelium. The mesenchymal population surrounding the endoderm is termed splanchnopleuric mesenchyme, and is produced by the splanchnopleuric coelomic epithelium (Fig. 12.2).

It is important to note that these terms are relevant only caudal to the third pharyngeal
arch. Rostral to this there is a sparse mesenchymal population between the pharynx and the surface ectoderm prior to migration of the head neural crest, and there are no landmarks with which to demarcate lateral from paraxial mesenchyme. This unsplit lateral plate is believed to contribute to the cricoid and arytenoid cartilages, the tracheal rings and the associated connective tissue.

**Somatopleuric mesenchyme**

Somatopleuric mesenchyme produces a mixed population of connective tissues and has a significant organizing effect at the level of the developing limbs. The pattern of limb development is controlled by information contained in the somatopleuric mesenchyme. Regions of the limb are specified by interaction between the surface ectoderm (apical ectodermal ridge) and underlying somatopleuric mesenchyme; together these tissues form the progress zone of the limb (see p. 899). The somatopleuric mesenchyme in the limb bud also specifies the postaxial border of the developing limb.

Somatopleuric mesenchyme thus gives rise to the connective tissue elements of the appendicular skeleton, including the pectoral and pelvic girdles and the bones and cartilage of the limbs and their associated ligaments and tendons. It also gives rise to the dermis of the skin of the ventral and lateral body walls and of the limbs.

Muscles of the limbs are derived from paraxially derived somitic precursor muscle cells.

**Splanchnopleuric mesenchyme**

Splanchnopleuric mesenchyme surrounds the developing gut and respiratory tubes, contributing connective tissue cells to the lamina propria and submucosa, and smooth muscle cells to the muscularis mucosae and muscularis externa. It plays a patterning role in endodermal development, specifying the region and villus type in the gut (see p. 1203), and the branching pattern in the respiratory tract (see p. 1032).

**Intermediate mesenchyme**

Intermediate mesenchyme is a loose collection of cells found between the somites and the lateral plate (Fig. 12.2). Its development is closely related to the progress of differentiation of the somites and the proliferating coelomic epithelium from which it is derived. Intermediate mesenchyme is not present before somitogenesis or the formation of the eighth somite. In embryos with eight to ten somites, it is present lateral to the sixth somite, but does not extend cranially. The mesenchyme cells are arranged as layers, one continuous with the dorsal side of the paraxial mesenchyme and the somatopleure, the other with the ventral side of the paraxial mesenchyme and the splanchnopleure.

As development proceeds, the intermediate mesenchyme forms a loosely packed dorsolateral cord of cells, which lengthens at the caudal end and ultimately joins the cloaca. It gives rise to the nephric system, gonads and reproductive ducts (see pp. 1305, 1311).

**Angioblastic mesenchyme**
Mesenchymal cells which give rise to the cellular elements of the blood, and the endothelium and mesenchymal layers of the tunica externa and adventitia of blood and lymphatic vessels, arise from extraembryonic and intraembryonic sources. Evidence suggests that endodermal tissues are necessary for endothelial differentiation. Angioblastic mesenchyme forms early in the third week of development from extraembryonic mesenchyme in the splanchnopleure of the yolk sac, in the body stalk (containing the allantois), and in the somatopleure of the chorion. The peripheral cells flatten as a vascular endothelium, whereas the central cells transform into primitive red blood corpuscles. Later, contiguous islands merge, forming a continuous network of fine vessels. Intraembryonic blood vessels are first seen at the endoderm–mesenchyme interface within the lateral splanchnic mesenchyme at the caudolateral margins of the cranial intestinal portal. Angioblastic competence has been demonstrated within the ventral (splanchnopleuric) mesenchymes with which the endoderm interacts. However, the notochord and prechordal plate do not contain angiogenic cells. Similarly, ectodermal tissues do not appear to give rise to angiogenic cells. Somites, derived from paraxial mesenchyme, have been shown to be a source of angioblasts which either differentiate with the somite derivatives, or migrate to the neural tube, ventrolateral body wall, limb buds, mesonephros and the dorsal part of the aorta.

The earliest angiogenic mesenchymal cells form blood vessels by vasculogenesis, a process in which new vessels (e.g. endothelial heart tubes, dorsal aortae, umbilical and early vitelline vessels) develop in situ. Later vessels develop by angiogenesis, sprouting and branching from the endothelium of pre-existing vessels; this process is the means by which most other vessels develop. The ultimate pattern of vessels is controlled by the surrounding, non-angiogenic mesenchyme: vessels become morphologically specific for the organ in which they develop and also immunologically specific, expressing organ-specific proteins.
REFERENCES

CHAPTER 13 – Early embryonic circulation

The early embryonic circulation is symmetrical (Fig. 13.1). It is modified throughout development to produce a functioning fetal circulation which is connected to the placenta, and changes rapidly at birth to accommodate disconnection from the placenta and the start of gaseous exchange in the lungs. Major restructuring of early vessels occurs as the embryo grows: anastomoses form and then disappear, capillaries fuse and give rise to arteries or veins, and the direction of blood flow may reverse several times before the final arrangement of vessels is completed.

The earliest circulatory components develop by vasculogenesis in the extraembryonic tissues. The endothelial heart tubes, dorsal aortae, umbilical and early vitelline vessels arise by vasculogenesis within the embryo. Further vessel development occurs by a process of angiogenesis in which angioblasts, arising in splanchnic and somitic tissues, add endothelial sprouts and branches to earlier vessels. None of the main vessels of the adult arises as a single trunk in the embryo. A capillary network is first laid down along the course of each vessel; the larger arteries and veins are defined by selection and enlargement of definite paths in this network. Lymphatic vessels develop after the main arteries and veins are formed: they arise initially by angiogenesis from the cardinal veins and subsequently by proliferation of lymphangioblasts to form lymphatic capillaries.

Early blood vessels are initially surrounded by a fibronectin-rich matrix that is later incorporated into the endothelial basal lamina along with laminin, a particularly early constituent. Several layers of fibronectin-expressing cells are seen around larger vessels, such as the dorsal aortae. The endothelium does not synthesize a basal lamina in those regions where remodelling and angiogenesis is active, and the mesenchyme around such endothelium does not express α-actin or laminin until branching has stopped and differentiation of the tunica media begins (after a stable vascular pattern has formed). It is not known how differentiation of pericytes and smooth muscle cells is induced; the majority of arteries accumulate medial smooth muscle from the surrounding mesenchyme.

In early development, the arteries of the embryo are disproportionately large and their walls consist of little more than a single layer of endothelium. The cardiac orifices are also relatively large and the force of the cardiac contraction is weak, and consequently the circulation is sluggish, despite the rapid rate of contraction of the developing heart. However, the tissues are able to draw nourishment not only from the capillaries but also from the large arteries and the intraembryonic coelomic fluid.

It has been suggested that the rapidly expanding cardiovascular system is filled with plasma by the movement of fluid from the intraembryonic coelom to the veins. In general, the wall of the intraembryonic coelom is composed of proliferating cells which produce the splanchnopleuric and somatopleuric mesenchymal populations. However, the walls of a portion of the pericardioperitoneal canals are thinner, and possibly more permeable to coelomic fluid, at the time when the canals surround the hepatocardiac channels (veins). The latter lie between the hepatic plexus and the sinus venosus; the hepatocardiac channel on the right side is more developed and on the left it is more plexiform, with only a transitory connection to the sinus venosus. The differentiation of this specific coelomic region occurs just in advance of the expansion and filling of the right and left atria, at about stage 12.
As the heart muscle thickens, compacts and strengthens, the cardiac orifices become both relatively and absolutely reduced in size, the valves increase their efficiency, and the large arteries acquire their muscular walls and undergo a relative reduction in size. From this time onwards, the embryo is dependent for its nourishment on the expanding capillary beds, and the function of the larger arteries becomes restricted to that of controllable distribution channels to keep the embryonic tissues constantly and appropriately supplied.

The heart starts to beat early, before the development of the conduction system, and a circulation is established before a competent valvular mechanism has formed. Cardiac output increases in proportion with the weight of the embryo and cardiac rate increases with development. However, most of the increase in cardiac output results from a geometric increase in stroke volume. When dorsal aortic blood flow is matched to embryonic weight, blood flow remains constant over a more than 150-fold change in mass of the embryo.

After head folding, the embryo has bilateral primitive aortae, each consisting of ventral and dorsal parts that are continuous through the first embryonic aortic arches (see Ch. 35). The ventral aortae are fused and form a dilated aortic sac. The dorsal aortae run caudally, one on each side of the notochord. In the fourth week they fuse from about the level of the fourth thoracic to that of the fourth lumbar segment to form a single definitive descending aorta (Figs 13.1A,C, 13.2B). In general, more mature endothelial channels are seen in the rostral, more advanced regions of the embryo, whereas more caudally, a changing capillary plexus constantly remodels until it becomes confluent with the vascular channels of the connecting stalk. The dorsal continuation of the primitive dorsal aortae directs blood into an anastomosing network around the allantois which will form the umbilical arteries. Blood is channelled back to the developing heart from the allantois via umbilical veins, from anastomoses in the primitive yolk sac via the vitelline veins, and from the body via pre- and post-cardinal veins that join to form the common cardinal veins (Figs 13.1B,C, 13.2A).

Fig. 13.1 The early, symmetrical blood vascular system. A, Ventrolateral view of the endothelial profile of the heart, the first
EMBRYONIC ARTERIES

Initially the dorsal aortae are the only longitudinal vessels present. Their branches all run at right angles to the long axis of the embryo. Later these transverse arteries become connected by longitudinal anastomosing channels which persist in part, forming arteries such as the vertebral, internal thoracic, superior and inferior epigastric, and gastroepiploic. Each primitive dorsal aorta gives off somatic arteries (intersegmental branches to the body wall), a caudal continuation which passes into the body stalk (the umbilical arteries), lateral splanchnic arteries (paired segmental branches to the mesonephric ridge), and ventral splanchnic arteries (paired segmental branches to the digestive tube).

Somatic arteries

The somatic arteries are intersegmental in position. They persist, almost unchanged, in the thoracic and lumbar regions, as the posterior intercostal, subcostal and lumbar arteries. Each gives off a dorsal ramus, which passes backwards in the intersegmental interval and divides into medial and lateral branches to supply the muscles and superficial tissues of the back (Fig. 13.3). The dorsal ramus also gives off a spinal branch, which enters the vertebral canal and divides into a series of
branches that supply the walls and joints of the osteoligamentous canal, and neural branches to the spinal cord and spinal nerve roots. After giving off its dorsal ramus, each intersegmental artery runs ventrally in the body wall, gives off a lateral branch and terminates in muscular and cutaneous rami.

Fig. 13.3 The segmental and intersegmental arteries. Note the positions of the longitudinal anastomoses (small red dilatations).

Early umbilical arteries
Initially, the umbilical arteries are the direct caudal continuation of the primitive dorsal
aortae. They are present in the body stalk before any vitelline or visceral branches emerge, indicating the dominance of the allantoic over the vitelline circulation in the human embryo. (On a comparative basis, the umbilical vessels are chorio-allantoic and therefore ‘somatovisceral’.) After the dorsal aortae fuse, the umbilical arteries arise from their ventrolateral aspects and pass medial to the primary excretory duct to the umbilicus. Later, the proximal part of each umbilical artery is joined by a new vessel that leaves the aorta at its termination and passes lateral to the primary excretory duct. This, possibly the fifth lumbar intersegmental artery, constitutes the dorsal root of the umbilical artery (the original stem, the ventral root). The dorsal root gives off the axial artery of the lower limb, branches to the pelvic viscera and, more proximally, the external iliac artery. The ventral root disappears entirely, and the umbilical artery now arises from that part of its dorsal root distal to the external iliac artery, i.e. the internal iliac artery.

Lateral splanchnic arteries

The lateral splanchnic arteries supply, on each side, the mesonephros, metanephros, testis or ovary and the suprarenal gland. All these structures develop, in whole or in part, from the intermediate mesenchyme, later termed the aorta-gonad-mesonephros region. One testicular or ovarian artery and three suprarenal arteries persist on each side. The phrenic artery branches from the most cranial suprarenal artery, and the renal artery arises from the most caudal. Additional renal arteries are frequently present and may be regarded as branches of persistent lateral splanchnic arteries.

Ventral splanchnic arteries

The ventral splanchnic arteries are originally paired vessels distributed to the capillary plexus in the wall of the yolk sac. After fusion of the dorsal aortae, they merge as unpaired trunks that are distributed to the increasingly defined and lengthening primitive digestive tube. Longitudinal anastomotic channels connect these branches along the dorsal and ventral aspects of the tube, forming dorsal and ventral splanchnic anastomoses (Fig. 13.3). These vessels obviate the need for so many ‘subdiaphragmatic’ ventral splanchnic arteries, and these are reduced to three, the coeliac trunk and the superior and inferior mesenteric arteries. As the viscera supplied descend into the abdomen, their origins migrate caudally by differential growth: the origin of the coeliac artery is transferred from the level of the seventh cervical segment to the level of the 12th thoracic; the superior mesenteric from the second thoracic to the first lumbar; and the inferior mesenteric from the twelfth thoracic to the third lumbar. However, above the diaphragm, a variable number of ventral splanchnic arteries persist, usually four or five, supplying the thoracic oesophagus. The dorsal splanchnic anastomosis persists in the gastroepiploic, pancreaticoduodenal and primary branches of the colic arteries, whereas the ventral splanchnic anastomosis forms the right and left gastric and the hepatic arteries.
EMBRYONIC VEINS

The early embryonic veins are often segregated into two groups, visceral and somatic, for convenience and apparent simplicity. The visceral group contains the derivatives of the vitelline and umbilical veins, and the somatic group includes all remaining veins. It should be noted that, with time, embryonic veins change the principal tissues they drain. They may receive radicles from obviously parietal tissues which become confluent with drainage channels that are clearly visceral, and so form a compound vessel. The arrangement of the early embryonic veins is initially symmetrical. The primitive tubular symmetric heart receives its venous return through the right and left sinual horns which are initially embedded in the mesenchyme of the septum transversum. Each horn receives, most medially, the termination of the principal vitelline vein, more laterally, the umbilical vein and, most laterally, having encircled the pleuroperitoneal canal, the common cardinal vein. This symmetric pattern changes as the heart and gut develop and the cardiac return is diverted to the right side of the heart.

Vitelline veins

The vitelline veins drain capillary plexuses developed in the splanchnopleuric mesenchyme of the secondary yolk sac. With head, tail and lateral fold formation, the upper recesses of the yolk sac are enclosed within the embryo as the splanchnopleuric gut tube, which extends from the stomodeal buccopharyngeal membrane to the proctodeal cloacal membrane. Derivatives from all these levels possess a venous drainage that is originally vitelline.

Early umbilical veins

The umbilical veins form by the convergence of venules that drain the splanchnopleure of the extraembryonic allantois. The human endodermal allantois is very small: it projects into the embryonic end of the connecting stalk, which is therefore regarded as precociously formed allantoic mesenchyme, whereas the umbilical vessels are considered to be allantoic. The peripheral venules drain the mesenchymal cores of the chorionic villous stems and terminal villi (extraembryonic somatopleuric structures). These are the radicles of the vena umbilicalis impar (usually single) which traverses the compacting mixed mesenchyme of the umbilical cord to reach the caudal rim of the umbilicus. Here, the single cordal vein divides into primitive right and left umbilical veins. Each curves rostrally in the somatopleuric lateral border of the umbilicus, i.e. where intraembryonic and extraembryonic or amniotic somatopleure are continuous, lying lateral to the communication between both the intraembryonic and extraembryonic coeloms. Rostrolateral to the umbilicus, the two umbilical veins reach, enter and traverse the junctional mesenchyme of the septum transversum and connect with septal capillary plexuses. They then continue, entering their corresponding cardiac sinual horns lateral to the terminations of the vitelline veins. This early symmetric disposition of the vitelline veins and anastomoses, umbilical and common cardinal veins, and the locus of the hepatic primordial complex are summarized in Figs 13.1B, 13.2A. For further development of the vitelline and umbilical veins see Chapter 73 (Figs 73.8, 73.9).

Cardinal veins and somatic venous complexes
The initial venous channels in the early embryo have traditionally been termed cardinal because of their importance at this stage. The cardinal venous complexes are first represented by two large vessels on each side, the precardinal portion being rostral and the postcardinal, caudal, to the heart. The two veins on each side unite to form a short common cardinal vein, which passes ventrally, lateral to the pleuropericardial canal, to open into the corresponding horn of the sinus venosus (Figs 13.1B, 13.2A, 13.4B). The precardinal veins undergo remodelling as the head develops. The postcardinal veins, which in the early embryo drain the body wall, are insufficient channels for venous return from the developing mesonephros and gonads and for the growing body wall. As the embryo increases in size, they are supplemented by a range of bilateral longitudinal channels that anastomose with the posterior cardinal system and with each other. These channels are the subcardinal, supracardinal, azygos line, subcentral and precostal veins (Fig. 13.4).
Subcardinal veins

Subcardinal veins form in the ventromedial parts of the mesonephric ridges and become connected to the postcardinal veins by a number of vessels traversing the medial part of the ridges. The subcardinal veins assume the drainage of the mesonephros, and intercommunicate by a pre-aortic anastomotic plexus, which later constitutes the part of the left renal vein that crosses anterior to the abdominal aorta.

Supracardinal veins

Supracardinal veins form dorsolateral to the aorta and lateral to the sympathetic trunk and take over the intersegmental venous drainage from the posterior cardinal vein. The supracardinal veins are also referred to as the thoracolumbar line or lateral sympathetic line veins.

Azygos line veins

Azygos line veins form dorsolateral to the aorta and medial to the sympathetic trunk. These channels, also referred to as the medial sympathetic line veins, gradually take over the intersegmental venous drainage from the supracardinal veins. The intersegmental veins now reach their longitudinal channel by passing medial to the autonomic trunk, a relationship that the lumbar and intercostal veins subsequently maintain. Cranially, the azygos lines join the persistent cranial ends of the posterior cardinal veins.

Subcentral veins

Subcentral veins form directly dorsal to the aorta in the interval between the origins of the paired intersegmental arteries. These veins communicate freely with each other and with the azygos line veins; these connections ultimately form the retro-aortic parts
of the left lumbar veins and of the hemiazygos veins.

A precostal or lumbocostal venous line

A precostal or lumbocostal venous line, anterior to the vertebrocostal element and posterior to the supracardinal, is recognized by some authorities. A possible derivative is the ascending lumbar vein.

Further development of the somatic veins

The supracardinal veins lie lateral to the aorta and the sympathetic trunks, which therefore intervene between them and the azygos lines (Fig. 13.4). They communicate caudally with the iliac veins and cranially with the subcardinal veins in the neighbourhood of the pre-aortic intersubcardinal anastomosis. The supracardinal veins also communicate freely with each other through the medium of the azygos lines and the subcentral veins. The most cranial of these connections, together with the supracardinal–subcardinal and the intersubcardinal anastomoses, complete a venous ring around the aorta below the origin of the superior mesenteric artery, termed the ‘renal collar’.

The ultimate arrangement of these embryonic abdominal and thoracic longitudinal cardinal veins may be summarized as follows. The terminal part of the left postcardinal vein forms the distal part of the left superior intercostal vein. On the right side, its cranial end persists as the terminal part of the azygos vein. The caudal part of the subcardinal vein is in part incorporated in the testicular or ovarian vein and partly disappears. The cranial end of the right subcardinal vein is incorporated into the inferior vena cava and also forms the right suprarenal vein. The left subcardinal vein, cranial to the intersubcardinal anastomosis, is incorporated into the left suprarenal vein. The renal and testicular or ovarian veins on both sides join the supracardinal–subcardinal anastomosis. On the left side, this is connected directly to the part of the inferior vena cava that is of subcardinal status via an intersubcardinal anastomosis. The right supracardinal vein forms much of the postrenal (caudal) segment of the inferior vena cava. The left supracardinal vein disappears entirely. The right azygos line persists in its thoracic part to form all but the terminal part of the azygos vein. Its lumbar part can usually be identified as a small vessel that leaves the vena azygos on the body of the 12th thoracic vertebra and descends on the vertebral column, deep to the right crus of the diaphragm, to join the posterior aspect of the inferior vena cava at the upper end of its postrenal segment. The left azygos line forms the hemiazygos veins. The subcentral veins give rise to the retro-aortic parts of the left lumbar veins and of the hemiazygos veins (Fig. 13.4).
EMBRYONIC LYMPHATIC VESSELS

The earliest lymphatic vessels arise from budding of lymphatic endothelial cells from the cardinal veins to form lymph sacs (Eichman et al 2005). Six early lymph sacs can be identified, two are paired (the jugular and the posterior lymph sacs) and two are unpaired (the retroperitoneal sac and the cisterna chyli). In lower mammals an additional pair (subclavian) is present, but in the human embryo these are merely extensions of the jugular sacs.

The jugular lymph sac is the first to appear, at the junction of the subclavian vein with the precardinal, with later prolongations along the internal and external jugular veins; the posterior lymph sac encircles the left common iliac vein; the retroperitoneal sac appears in the root of the mesentery near the suprarenal glands; and the cisterna chyli appears opposite the third and fourth lumbar vertebrae (Fig. 13.5). The lymph vessels bud out from the lymph sacs along lines that correspond more or less closely with the course of embryonic blood vessels (most commonly veins); many also arise de novo in the mesenchyme and establish connections with existing vessels. In the body wall and the wall of the intestine, the deeper plexuses are the first to be developed; the vessels in the superficial layers are gradually formed by continued growth.
Fig. 13.5 Relative positions of the primary lymph sacs (as originally determined by Sabin, 1912).
LYMPH NODES AND LYMPHOID TISSUES

Lymph vessels can be seen in the embryo in the cervical region from stage 16. Lymph nodes, which provide regional proliferative foci for lymphocytes, have been identified from week 9. Early lymph sacs become infiltrated by lymphoid cells, and the outer portion of each sac becomes the subcapsular sinus of the lymph node. Morphological differentiation of medullary and cortical compartments has not been observed until the end of week 10 (Tonar et al. 2001). At the same time as these early lymph nodes are developing, the nasopharyngeal wall is infiltrated by lymphoid cells that are believed to herald the early development of the tubal and pharyngeal tonsils.

In the neonate, a considerable proportion of the total amount of lymphoid tissue is localized in lymph nodes: the subsequent increase in the amount of lymphoid tissues that occurs during childhood reflects the growth of these nodes. Definitive follicles with germinal centres are formed during the first postnatal year. The pharyngeal tonsil reaches its maximal development at 6 years and its subsequent involution is completed by puberty. Details of the development of gut-associated lymphoid tissue are given in Chapter 73.

CHAPTER 14 – Pre- and postnatal development

PRENATAL STAGES

The absolute size of an embryo or fetus does not afford a reliable indication of either its chronological age or the stage of structural organization, even though graphs based on large numbers of observations have been constructed to provide averages. All such data suffer from the difficulty of timing the moment of conception in humans. It has long been customary to compute the age, whether in a normal birth or an abortion, from the first day of the last menstrual period of the mother but, as ovulation usually occurs near the 14th day of a menstrual cycle, this ‘menstrual age’ is an overestimate of about 2 weeks. Where a single coitus can be held to be responsible for conception, a ‘coital age’ can be established and the ‘fertilization age’ cannot be much less than this, because of the limited viability of both gametes. It is usually held that the difference may be several days, which is a highly significant interval in the earlier stages of embryonic development. Even if the time of ovulation and coitus were known in instances of spontaneous abortion, not only would some uncertainty still persist with regard to the time of fertilization, but there would also remain an indefinable period between the cessation of development and the actual recovery of the conceptus.

To overcome these difficulties, early embryos have been graded or classified into developmental stages or ‘horizons’, on the basis of both internal and external features. The study of the Carnegie collection of embryos by Streeter (1942, 1945, 1948), and the continuation of this work by O’Rahilly & Müller (1987), provided, and continues to provide, a sound foundation for embryonic study and a means of comparing stages of human development with those of the animals routinely used for experimental study, namely the chick, mouse and rat. Recent use of ultrasound for the examination of human embryos and fetuses in utero has confirmed much of the staging data.

The development of a human from fertilization to birth is divided into two periods, embryonic and fetal. The embryonic period has been defined by Streeter as 8 weeks postfertilization, or 56 days. This timescale is divided into 23 Carnegie stages, a term introduced by O’Rahilly & Müller (1987) to replace developmental ‘horizons’. The designation of stage is based on external and internal morphological criteria and not on length or age.

Embryonic stages

Embryonic stages 1–10 are shown in detail in Fig. 8.1. It should be noted that estimations of embryonic length may be 1–5 mm less than equivalent in vivo estimates, reflecting the shrinkage caused by the fixation procedures that are inevitably used in embryological studies. O’Rahilly & Müller (2000) have revised some of the ages that were previously assigned to early embryonic stages, pointing out that inter-embryonic variation may be greater than had been thought and that consequently some ages may have been underestimated. They note that as a guide, the age of an embryo can reasonably be estimated from the embryonic length within the range 3–30 mm, by adding 27 to the length. Correlating the age of any stage of development to an approximate day may be unreliable, and a generalization using the number of weeks of development might be now more appropriate.
The stages of development encompass all aspects of internal and external morphogenetic change that occur within the embryo within the duration of the stage. They are used to convey a snapshot of the status of the development of all body systems within a particular timeframe. Figure 14.1 shows the external appearance of embryos from stage 6 to stage 23, with details of their size and age in days. The correlation of external appearance of the embryo with internal development is shown in Fig. 14.2.

**Fig. 14.1** The external appearance and size of embryos between stages 6 and 23. Early in development, external features are used to describe the stage, e.g. somites, pharyngeal arches or limb buds.

(Adapted by permission from Rodeck CH, Whittle MJ 1999 Fetal Medicine. London: Churchill Livingstone.)
Historically, the onset of bone marrow formation in the humerus was used by Streeter to indicate the end of the embryonic and the beginning of the fetal period of prenatal life. The fetal period occupies the remainder of intrauterine life: growth is accentuated, although differentiative processes continue up to and beyond birth. Overall, the fetus increases in length from 30 mm to 500 mm, and increases in weight from 2–3 g to more than 3000 g.

Fetal staging

Currently there is no satisfactory system of morphological staging of the fetal period of development, and the terminology used to describe this time period reflects this confusion. The terms ‘gestation’, ‘gestational age’ and ‘gestational weeks’ are considered ambiguous by O’Rahilly & Müller (2000) who recommend that they should be avoided. However, they are widely used colloquially within obstetric practice. Staging of fetal development and growth is based on an estimate of the duration of a pregnancy. Whereas development of a human from fertilization to full term averages 266 days, or 9.5 lunar months (28 day units), the start of pregnancy is traditionally determined clinically by counting days from the last menstrual period; estimated in this manner, pregnancy averages 280 days, or 10 lunar months (40 weeks). Figure 14.3 shows the embryonic timescale used in all descriptions of embryonic development and the obstetric timescale used to gauge the stage of pregnancy. Studies that
discuss fetal development and the gestational age of neonates, particularly those born before 40 weeks' gestation, use the clinically estimated stages and age unless they specifically correct for this. If a fetal ageing system is used, it must be remembered that the age of the fetus may be 2 weeks more than a comparable fetus that has been aged from postovulatory days.

The predicted date of full term and delivery is revised after routine ultrasound examination of the fetus. Early ultrasound estimation of gestation increases the rate of reported preterm delivery (delivery at <37 weeks) compared with estimation based on the date of the last menstrual period (Yang et al 2002), possibly because delayed ovulation is more frequent than early ovulation: the predicted age of a fetus estimated from the date of the last menstrual period may differ by more than 2 weeks from estimates of postfertilization days.

A number of biometric indices used to determine fetal growth in utero have been evaluated ultrasonographically; the consensus appears to be that some revision of gestational age may be required when using charts based on fetal biometry, and that using fewer biometric variables for the estimation produces a larger standard error. First-trimester growth charts based on biparietal diameter, head circumference and abdominal circumference of normal singleton fetuses correlated against crown–rump length (from 45 to 84 mm) are said to be more accurate than gestational age (Salomon et al 2003). O'Rahilly & Müller (2000) recommend that the term 'crown–rump length' should be replaced by greatest length, exclusive of lower limbs in ultrasound examination. Femur length/head circumference ratio may be a more robust ratio to characterize fetal proportions than femur length/biparietal diameter (Johnsen et al 2005), and combining kidney length, biparietal diameter, head circumference and
femur length also increases the precision of dating (Konje et al 2002). Johnsen et al (2004) reported that analysis of measurements of biparietal diameter and head circumference at 10–24 weeks gestation gave a gestational age assessment of 3–8 days greater than charts in present use.

Constructions of ultrasound biometry charts for fetal aging now take into account the ethnic population under consideration and it is recommended that locally developed charts specific to the population should be used. The use of these charts means that factors that may influence fetal biometry, including maternal age and nutritional status, can be identified, facilitating accurate prediction of small-for-date and growth-retarded fetuses.

Although accurate morphological stages are not available for the fetal period, the developmental progression is broadly clear. During the fourth and fifth months, the fetus has a head and upper limbs that are still disproportionally large. Although the rates of growth of the trunk and lower limbs increase during the remainder of intra-uterine life, the disproportion is present after birth and, to a diminishing degree, is retained throughout childhood and on into the years of puberty. A covering of primary hair, lanugo, appears. Towards the end of this period, sebaceous glands become active; the sebum that is secreted blends with desquamated epidermal cells to form a cheesy covering over the skin, the vernix caseosa, that is usually considered to protect the skin from maceration by the amniotic fluid. About this time the mother, becomes conscious of fetal movement, formerly termed ‘quickening’.

In the sixth month, the lanugo darkens, the vernix caseosa is more abundant and the skin becomes markedly wrinkled. The eyelids and eyebrows are now well developed. During the seventh month, the hair of the scalp is lengthening and the eyebrow hairs and the eyelashes are well developed. The eyelids themselves separate and the pupillary membrane disappears. The body becomes more plump and rounded in contour and the skin loses its wrinkled appearance as a result of the increased deposition of subcutaneous fat. Fetal length has increased to approximately 350 mm and weight to about 1.5 kg. Towards the end of this month the fetus is viable: if born prematurely it is able to survive without the technological assistance found in Neonatal Intensive Care Units and its postnatal development can proceed normally.

Throughout the remaining lunar months of normal gestation, the covering of vernix caseosa is prominent. There is a progressive loss of lanugo, except for the hairs on the eyelids, eyebrows and scalp. The bodily shape is becoming more infantile but, despite some acceleration in its growth, the leg has not quite equalled the arm in length proportionately, even at the time of birth. The thorax broadens relative to the head, and the infra-umbilical abdominal wall shows a relative increase in area, so that the umbilicus gradually becomes more centrally situated. Average lengths and weights for the eighth, ninth and tenth months are 40, 45 and 50 cm and 2, 2.5 and 3–3.5 kg, respectively. The rate of fetal growth slows from 36 to 40 weeks in response to the physical limitation imposed by the maternal uterus. Birth weight thus reflects the maternal environment more than the genotype of the child. This slowing of the growth rate enables a genetically larger child developing within a small mother to be delivered successfully. After birth, the growth rate of the neonate increases and the rate of weight gain, reaches a peak some 2 months postnatally.

Just before birth, the lanugo almost disappears, the umbilicus is central. The testes,
which begin to descend with the processus vaginalis of peritoneum during the seventh month and are approaching the scrotum in the ninth month, are usually scrotal in position. The ovaries are not yet in their final position at birth; although they have attained their final relationship to the uterine folds, they are still above the level of the pelvic brim.

**Obstetric stages**

In obstetric practice the duration of the period of gestation is regarded as nine calendar months, which is approximately 270 days. The period of pregnancy is divided into thirds, termed trimesters. The first and second trimesters each cover a period of 12 weeks, and the third trimester covers the period from 24 weeks to delivery. Although the expected date of delivery is computed at 40 weeks of pregnancy, the term of the pregnancy, i.e. its completion resulting in delivery, is considered normal between 37 and 42 weeks. Neonates delivered before 37 weeks are called preterm (or premature); those delivered after 42 weeks are post-term. The period from the end of week 24 and up to 7 days after birth, is termed the perinatal period. Fetuses that are delivered and die before 24 weeks are considered to be miscarriages of pregnancy, although technological advances in neonatal care can now assist the delivery and support of infants younger than 24 weeks. Infants born after 24 weeks of pregnancy which subsequently die are classed as stillborn and contribute to the statistics of perinatal mortality.
THE NEONATE

The neonatal period extends from birth to 28 days postnatally, and is divided into an early neonatal period from birth to 7 days, and a late neonatal period from 7 to 28 days.

In Western societies, technological advances have enabled successful management of preterm infants, many at ages that were considered non-viable a decade or two previously. Maturational processes involving local interactions and pattern formation still drive development at local and body-system levels in preterm infants. The sudden release of such fetuses into a gaseous environment, of variable temperature, with full gravity and a range of microorganisms, promotes the rapid maturation of some systems and the compensatory growth (in terms of responses to the effect of gravity or enteral feeding or exposure to microorganisms), of others. To understand the multitude of mechanisms that operate within a newly delivered fetus, as much information as possible concerning normal embryological and fetal development is required.

Details of the relative positions of the viscera and the skeleton in a full term neonate are shown in Figs 14.4–14.6. The newborn infant is not a miniature adult, and extremely preterm infants are not the same as full-term infants. There are immense differences in the relations of some structures between the full-term neonate, child and adult, and there are also major differences between the 20-week gestation fetus and the 40-week fetus, just before birth. The study of fetal anatomy at 20, 25, 30 and 35 weeks is vital for the investigative and life-saving procedures carried out on preterm infants today.
Fig. 14.4  A–C. Topographical representation of the anatomy of a full-term neonate. The surface markings of all organs are shown, with some coloured and others only in outline. The female genital tract is shown on the right of the body, with the male tract on the left.
Fig. 14.5 Topographical representation of the anatomy of a full-term female neonate. The cut surfaces of the organs are the same colours as in Fig. 14.4.
Fig. 14.6 The extent of the ossified skeleton in the full term neonate. Note the derivation of the parts of the skeleton: the skull is derived from paraxial mesenchyme and neural crest mesenchyme; the axial skeleton, vertebrae and ribs are derived from paraxial mesenchyme; the skeletal elements in the limbs are derived from the somatopleuric mesenchyme, which forms the limb buds.

Neonatal measurements and period of time in utero

The 10th to 90th centile ranges for length of full-term neonates are 48–53 cm (Fig. 14.7A). Length of the newborn is measured from crown to heel. In utero, length has been estimated either from crown–rump length, i.e. the greatest distance between the vertex of the skull and the ischial tuberosities, with the fetus in the natural curved position, or from the greatest length exclusive of the lower limbs. Greatest length is independent of fixed points and thus much simpler to measure. It is generally taken to be the sitting height in postnatal life, and is the measurement recommended by O’Rahilly & Müller (2000) as the standard in ultrasound examination. The 10th to 90th
centile ranges for weight of the full-term infant at parturition ranges are 2700–3800 g (Fig. 14.7B), the average being 3400 g; 75–80% of this weight is body water and a further 15–28% is composed of adipose tissue. After birth, there is a general decrease in the total body water, but a relative increase in intracellular fluid. Normally, the newborn loses about 10% of its birth weight by 3–4 days postnatally, because of loss of excess extra-cellular fluid and meconium. By 1 year, total body water makes up 60% of the body weight.

Low birth weight has been defined as less than 2500 g, very low birth weight as less than 1500 g, and extremely low birth weight as less than 1000 g. Infants may weigh less than 2500 g but not be premature by gestational age. Measurement of the range of weights that fetuses may attain before birth has led to the production of weight charts, which allow babies to be described according to how appropriate their birth weight is for their gestational age, e.g. small for gestational age, appropriate for gestational age or large for gestational age (Fig. 14.8). Small for gestational age infants, also termed ‘small-for-dates’, are often the outcome of intrauterine growth retardation. The causes of growth restriction are many and various and beyond the scope of this text.
Intrauterine growth status and its appropriateness for gestational age. Gestational age is more closely related to maturity than birth weight. The mortality for the weight ranges is indicated.

For both premature and growth-retarded infants, an assessment of gestational age, which correlates closely with the stage of maturity, is desirable. Gestational age at birth is predicted by its proximity to the estimated date of delivery and the results of ultrasonographic examinations during pregnancy. It is currently assessed in the neonate by evaluation of a number of external physical and neuromuscular signs. Scoring of these signs results in a cumulative score of maturity that is usually within ±2 weeks of the true age of the infant. The scoring scheme has been devised and improved over many years. For an account of methods of assessing gestational age in neonates, consult Gandy (1992).
INTEGRATION OF TYPES OF GROWTH DURING DEVELOPMENT

In the later prenatal months and in the postnatal period, the various types of growth occur in differing patterns. The extent of tissue growth in organs depends on the specific duration of multiplicative growth for the cell types (Fig. 14.9). Different cell populations complete their initial developmental proliferation and become differentiated at different times, the final stage of differentiation usually being cessation of cell division.

Growth of a body can be described in two ways, isometric and allometric. Isometric growth implies a progressive proportional increase in all organs and systems with time: it does not occur in the developing embryo, which displays differential rates of
Allometric growth describes the differences in the relative rates of growth between one part of the body and another, and is most clearly seen in the changes in body proportion between fetuses, neonates, children and adults. Between 6 and 7 weeks after fertilization, the head is nearly one-half of the total embryonic length. It subsequently grows proportionally more slowly, and at birth it is one-quarter of the entire length. During childhood, this pattern of growth continues with lengthening of the torso and limbs until, in adults, the head is one-eighth the length (Fig. 14.10).

Fig. 14.10 Allometric growth in humans. The head is very large in proportion to the rest of the body during the embryonic period. After this time the head grows more slowly than the torso and limbs and by adulthood the head is only one-eighth of the body length.

Growth of the liver, spleen and kidneys, and skeletal and muscular tissues generally follow pre- and postnatal growth curves given for the entire body. Other tissues have very different growth rates; the brain, skull, lymphoid tissues and reproductive organs all show differing growth rates during childhood and adolescence (Fig. 14.11).
The amount and distribution of adipose tissue within the body change with age and hormonal status. Subcutaneous fat deposits are estimated by measurements taken by calipers applied to a fold of fat pinched up from the underlying muscles, usually over triceps and beneath the angle of the scapula. Fat is laid down in the fetus from about 34 weeks, and the amount increases to the 9th postnatal month. After this time subcutaneous fat decreases (i.e. it has a negative growth velocity), until 6–8 years, when it begins to increase again. This early decrease in fat is less marked in girls than in boys so that, after 1 year, girls have more fat than boys. From 7 years the increase in fat occurs in both sexes. At adolescence, the limb fat in boys (triceps measurement)
decreases, and is not regained until the late 20s, whereas girls show a slight slowing of the increase in limb fat, but no loss. At this time the trunk fat (subscapular measurement) stops increasing in boys, but shows a steady increase in girls. Postpubertal girls, but not boys, show fat deposits in a secondary sexual distribution, i.e. in the breasts, over the upper arms, lower abdomen and thighs. Adult men are more likely to deposit fat around the anterior abdominal wall.
GROWTH IN UTERO

Alterations in the availability of nutrients to the fetus at particular stages of pregnancy elicit adaptive responses by the fetus that ensure fetal coping, but which may result in pathology in adult life: the nutritional status of pregnant women is therefore of fundamental importance for the health of the next generation. For example, poor nutrition at critical stages of fetal life may permanently alter the normal developmental pattern of a range of organs and tissues, e.g. the endocrine pancreas, liver and blood vessels, resulting in their pathological responses to certain conditions in later adult life (Barker et al 1993). An increase in placental size occurs in pregnancy as an adaptive response to both high altitude and mild undernutrition, particularly during mid-pregnancy. However, although a larger placenta may be better able to deliver the full nutritional requirements of the fetus, the perfusion of a larger placenta is not without problems. It may produce changes in fetal blood flow and placental enzymes, and in the normal structure of the fetal vessel wall or of its responses to circulating trophins, e.g. catecholamines or angiotensin II, which will continue into adult life. Undernutrition in later pregnancy does not produce the same sequelae and placental enlargement does not occur. However, fetal growth slows and fetal wasting may occur as oxygen, glucose and amino-acids are redistributed to the placenta to maintain its function.

Maternal starvation during pregnancy decreases fetal IGF-I concentrations, and this may, along with a general hypoglycaemia, impair the development of the fetal β cells of the pancreas. Moreover, fetal undernutrition may induce insulin resistance in the tissues. The coexistence of insulin resistance and impaired β-cell development in the fetus appears to be important in the pathogenesis of non-insulin-dependent diabetes. The risk of developing this ‘type 2’ diabetes is greatest in those individuals with low weight at birth and at 1 year, and who become obese as adults, thus challenging an already impaired glucose–insulin metabolism. Fetal IGF-I concentrations are also lower in infants who are short at birth as a result of a long period of maternal undernutrition: these individuals have an exaggerated responses to growth hormone-releasing factor, which, together with low IGF-I concentrations, suggests a degree of growth hormone resistance.

It is now thought that the balance of hormonal environment in intrauterine and early postnatal life is necessary for future adult health. The presence of altered concentrations of hormones during critical periods of development may act as endogenous functional teratogens (Plagemann 2004).

Different birth phenotypes have been correlated with different pathological sequelae. Infants who are thin at birth, with a low ponderal index (weight/length$^3$), tend to develop a combination of insulin resistance, hypertension, non-insulin-dependent diabetes and lipid dis-orders, whereas
those who are short in relation to head size tend to develop hypertension and high plasma fibrinogen concentrations. These associations have been reported in babies born small for dates, rather than in those born prematurely. Some babies of average weight also develop cardiovascular pathology: they were either small at birth in relation to the size of their placenta, and thin at birth or, although of average weight, were short in relation to head size and had below average weight gain during the first year (Barker et al 1993). For more recent views on this concept the reader is directed to consult Godfrey & Barker (2000) and Gluckman et al (2005).
GROWTH IN CHILDHOOD

The rates of prenatal and postnatal growth can be indicated by increments in body length or weight which, when plotted, form a growth curve (see Fig. 14.7). Growth curves can be plotted for individuals if accurate measurements are taken, preferably by the same person, for the entire period of growth, i.e. a longitudinal study. An alternative method is to collect a series of averages for each year of age obtained from different individuals, i.e. a cross-sectional study. Cross-sectional studies are valuable for the construction of standards for height and weight attained by healthy children at specific ages, and can establish percentile limits of normal growth, but they cannot reveal individual differences in either the rate of growth or the timing of particular phases of growth.

The data from longitudinal and cross-sectional studies can also be used to plot the increments in height or weight from one age to the next. This produces a velocity curve, which reflects a child’s state at any particular time much better than the growth curve, in which each point is dependent on the preceding one. The oldest published longitudinal study, still of great value today, was made by Count Philibert de Montbeillard on his son (Fig. 14.12). It shows that the velocity of growth in height decreases from birth onwards, and that a marked acceleration of growth, the adolescent growth spurt, occurs from 13 to 15 years (see below; Fig 14.13).

![Fig. 14.12 A longitudinal study of growth. A, The height of de Montbeillard’s son (1759–1777) from birth to 18 years. B, A growth velocity curve, plotting increments in height from year to year. (After D’Arcy Thompson, On Growth and Form, 1942, Cambridge University Press.)](image)
Cross-sectional data permit comparison of prenatal and postnatal growth. Childhood growth charts are used to predict normal childhood development. The velocity curve for the prenatal and postnatal period (Fig. 14.14) shows that the peak velocity for length is reached at about 4 months (note that these prenatal charts use the obstetric measurements of gestational time, in which fetal age is estimated from the last menstrual period, 2 weeks before fertilization). Growth in weight usually reaches its peak velocity after birth.
Growth has always been regarded as a regular process. Tanner (in Harrison et al 1964) noted that the more carefully measurements are taken, the more regular is the succession of points on a growth curve. However, a longitudinal study of growth measured weekly, semi-weekly and daily, recorded that growth in length and head circumference occurred by saltatory increments, with a mean amplitude of 1.01 cm for length (Lampl 2002); growth stasis, steep changes in growth and incremental growth have all been recorded in infancy, childhood and adolescence (Caino et al 2006).

Charts of height and weight correlated to age are compiled from extensive cross-sectional growth studies. Such charts show the mean height or weight attained at
each age, termed the 50th centile, and also the centile lines for the 75th, 90th and 97th centiles, in addition to the 25th, 9th and 2nd centiles. The data shown in Fig. 14.15 are derived from United Kingdom cross-sectional references. Any comparison of an individual growth curve with these data must also take into account ethnicity and the nutritional and family history of that individual.

Fig. 14.15 Standard growth charts of boys and girls showing the 90th, 50th and 10th centiles. (© Child Growth Foundation.)

Plotting the growth of children on such charts provides guidelines for the prediction of normal growth and indicates when investigation of possible growth abnormalities should occur. Children who grow in an environment that does not constrain their growth exhibit a pattern of growth that is mainly parallel to a particular centile, a phenomenon that has been termed homeorhesis or canalization (following the same
imaginary 'canal' on the growth chart). After deviation from this centile as a consequence of the adolescent growth spurt, most children return to the same centile position in adulthood, a finding that suggests that this pattern is genetically determined within individuals (Cameron 2002). For a comprehensive account on all aspects of postnatal growth the reader is directed to consult Human Growth and Development (Cameron 2002).
ADOLESCENT GROWTH SPURT

Growth charts reveal that body length increases from a neonatal range of 48–53 cm to about 75 cm during the first year after birth, and increases by 12–13 cm in the second year. Thereafter, 5–6 cm is added each year. In individual longitudinal growth curves, an increase in the velocity of growth occurs between 10.5 and 11 years in girls, and 12.5 and 13 years in boys. This rapid increase in growth is the adolescent growth spurt (Figs 14.13 and 14.15). In both sexes it lasts for 2–2.5 years. Girls gain about 16 cm in height during the spurt, with a peak velocity at 12 years of age. Boys gain about 20 cm in height (mostly by growth of the trunk), with a peak velocity at 14 years of age, during which time they may be growing at the rate of 10 cm a year.

Humans seem to be the only species to have a long quiescent interval between the rapid growth that takes place immediately after birth and the adolescent growth spurt. It has been suggested that this period allows the brain to mature, and learning to take place, before individuals pass through puberty and become sexually active.

Growth in height continues at a slower rate after the adolescent growth spurt. Noticeable growth is said to stop at 18 years in females and 20 years in males (longitudinal studies have indicated that an average figure for this is 16.25 years for girls and 17.75 years for boys, with a normal variation of ±2 years (Harrison et al 1964)). After this time, any increments that occur as a result of appositional growth at the cranial and caudal ends of the vertebral bodies and intervening intervertebral discs are so small as to be difficult to measure. There is a loss of height after middle age.

The phenomenal growth rates of adolescence are most obvious in the increase in height. Weight gain is more variable. At birth, weight reflects the maternal environment, the number of conceptuses, the sex of the baby and the parity of the mother. Generally, full-term female babies are lighter than full-term males, twins are lighter than singletons, and later children tend to be heavier than the first-born. Although the birth weight seems to be independent of the maternal diet, unless there has been severe malnutrition, mothers in lower socioeconomic groups have smaller babies than those with a higher rating, and small mothers tend to have small babies.

The birth weight is normally tripled by the end of the first year, and quadrupled by the end of the second year. Thereafter, weight increases by 2.25–2.75 kg annually until the adolescent growth spurt, when boys may add 20 kg to their weight and girls 16 kg. The peak velocity for weight gain lags behind the peak velocity for height by about 3 months. Body weight does not reach adult values until some time after adult height is attained.

Section 3 – NEUROANATOMY

CHAPTER 15 – Overview of the nervous system

The human nervous system is the most complex product of biological evolution. The constantly changing patterns of activity of its billions of interactive units represent the fundamental physical basis of every aspect of human behaviour and experience. Many thousands of scientists and clinicians around the world, whether driven by intellectual curiosity or the quest for better methods of disease prevention and treatment, have studied the nervous system over many years. Despite the enormous amount of data available, our understanding of complex neural organization and function is far from complete, as is our ability to deal with its many pathologies. Nevertheless, research on the nervous system is one of the most active areas of contemporary biology and medicine and rapid advances on numerous fronts bring with them the realistic prospect of better prevention and treatment of many neurological disorders in the future.

The functional capabilities of the nervous system are a product of its vast population of intercommunicating nerve cells or neurones, estimated to number in the order of $10^{10}$ (Ch. 3). In brief, neurones encode information, conduct it, sometimes over considerable distances, and then transmit it to other neurones or to non-neural tissues such as muscles or glandular cells. Most neurones consist of a central mass of cytoplasm within a limiting cell membrane, the cell body or soma, from which extend a number of branched processes, or neurites (Fig. 15.1). One of these, the axon, or nerve fibre, is usually much longer than the others and conducts information away from the cell body. The other processes are termed dendrites and these typically conduct information towards the soma (cell body). The nerve cell membrane is polarized, the inside of the cell being around $-70$ mV negative with respect to the outside. Information is coded in the form of patterns of transient depolarizations and repolarizations of this membrane potential, known as action potentials or nerve impulses. These are conducted along the axon, which may have collateral branches that permit information to be distributed simultaneously to several targets. Axons possess specialized endings, or axon terminals, which come into close apposition with the membrane of the target cell at synapses, where information passes from one cell to another (Fig. 15.2). Axon terminals may form synaptic contacts with dendrites (axodendritic), cell bodies (axosomatic), other axons (axoaxonic) or non-neural tissue such as muscle cells (neuromuscular junction). Transmission of information to other cells occurs when action potentials cause the release of specific neurotransmitter substances, stored in synaptic vesicles within the presynaptic nerve terminal. The neurotransmitter binds to specialized receptors that are located on the postsynaptic target cell membrane and, depending upon the nature of the chemical and the receptor, either elicits an excitatory (depolarizing) or inhibitory (hyperpolarizing) response, or may modulate intracellular second messenger systems.

The huge complexity of the nervous system reflects the fact that individual neurones may make synaptic contact with hundreds, or even thousands, of other neurones via profuse axonal collateralization and dendritic branching (arborization). The latter is exemplified by the extensive dendritic field of the cerebellar Purkinje cell, which is traversed by thousands of axons, making synaptic contact as they pass. At the level of the individual neurone, competing incoming excitatory and inhibitory synaptic
potentials are summated in time (temporal summation) and between synapses (spatial summation). If the postsynaptic neurone is depolarized above a certain threshold it fires action potentials which are conducted along the axon to the next target cells.

The nervous system contains far more supporting cells (neuroglia, glia) than neurones. Glia are responsible for creating and maintaining an appropriate environment in which neurones can operate efficiently. Subsets of glia secrete the myelin sheaths that enwrap axons in many parts of the nervous system. Glia are not electrically excitable in the same way as neurones.

The three basic functional types of neurones in the nervous system, sensory (afferent) and motor (efferent) neurones and interneurones, detect and respond to changes in the internal and external environments of the body. The sensory elements are able to detect a wide range of stimuli: they subserve the general senses (touch, pain, temperature, etc.) and the special senses (vision, hearing, smell, taste, and vestibular sensation). Motor neurones send axons from the central nervous system to effector organs, mainly muscles and glands. Interneurones are confined entirely to the central nervous system and possess neither sensory nor motor terminals: they greatly outnumber sensory and motor neurones and confer on the nervous system its prodigious capacity to analyse, integrate and store information.

The nervous system is conventionally divided into two major parts, the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS consists of the brain and spinal cord. The PNS consists of the cranial and spinal nerves and their ramifications, and certain groupings of cell bodies that constitute the peripheral ganglia. Another convention divides the nervous system into somatic and autonomic components, with elements in both the CNS and PNS. The somatic nervous system controls the contraction of skeletal muscles. The autonomic nervous system, which may be subdivided into sympathetic and parasympathetic components, consists of neurones that innervate secretory glands, cardiac and smooth muscle and are therefore concerned primarily with control of the internal environment. Neurones in the wall of the gastrointestinal tract form the enteric nervous system, and are capable of sustaining local reflex activity that is independent of the CNS (Ch. 73).

CENTRAL NERVOUS SYSTEM

The brain and spinal cord (see Fig. 43.1A) contain the great majority of neuronal cell bodies in the nervous system. In many parts of the CNS, neuronal cell bodies are grouped together and are, more or less, segregated from axons. The generic term for such collections of cell bodies is grey matter. Small aggregations of neuronal cell bodies, which usually share a common functional role, are termed nuclei. Neuronal dendrites and synaptic interactions are mostly confined to grey matter. Axons tend to be grouped together to form white matter, so called because axons are often ensheathed in myelin which confers a paler colouration. Axons that pass between similar origins or destinations within the CNS tend to run together in defined pathways, or tracts. These often cross the midline (decussate), which means that one half of the
The body is, in many respects, controlled by, and sends information to, the opposite side of the brain.

Some groups of neurones in the spinal cord and brain stem that subserve similar functions are organized into longitudinal columns. The neurones in these columns may be concentrated into discrete, discontinuous nuclei in some areas, e.g. the cranial nerve nuclei of the brain stem, or they may form more or less continuous longitudinal bands, as in much of the spinal cord (Fig. 15.3). Efferent neurones constitute three such columns. The axons of motor neurones in the somatic motor column innervate muscles derived from head somites. The two other columns are related to specialized features of head morphology: neurones in the branchial motor column innervate muscles derived from the wall of the embryonic pharynx (branchial muscles) and the visceral motor column supplies preganglionic parasympathetic fibres to glands and visceral smooth muscle. Four longitudinal cell columns are related to sensory functions. The general somatic sensory column essentially deals with general sensory information from the head; special somatic sensory neurones are related to the special senses and receive vestibular and auditory input; general visceral sensory neurones deal with information from widespread and varied visceral sensory endings; special visceral sensory neurones are related to the special sense of taste.
Fig. 15.3 Arrangement of sensory and motor cell columns in the spinal cord and brain stem. In each of parts A, B and C, dorsal is towards the top of the diagram. A shows the organization of the primitive spinal cord with a dorsal sensory column, a ventral motor column, and segmentally arranged dorsal and ventral nerve roots. B depicts the adult thoracic spinal cord with sensory and somatic motor columns and an additional intermediate (lateral) visceral motor column. C indicates the arrangement of multiple longitudinal columns in the brain stem, where the motor column is now subdivided into three, and the sensory column into four. For further information about the embryological aspects of the early nervous system consult Ch. 24. Consult also Fig 19.1.

The brain and spinal cord communicate with the rest of the body via the cranial and spinal nerves respectively. These nerves contain afferent fibres that bring information into the CNS from sensory receptors, and efferent fibres that convey instructions from the CNS to peripheral effector organs. The spinal cord and brain stem can control many aspects of bodily function by reflex action mediated via interconnections of varying complexity between the afferent and efferent components of the spinal and cranial nerves. Numerous descending connections from the brain may modulate this activity. Afferent input to the spinal cord and brain stem is channelled into various
ascending pathways, some of which eventually impinge upon the cerebral cortex, conferring conscious awareness.

To provide the energy required by constant neuronal activity, the CNS has a high metabolic rate and a rich blood supply (Ch. 17). A blood–brain barrier controls the neuronal environment and imposes severe restrictions on the types of substances that can pass from the bloodstream into nervous tissue (Ch. 3).

**SPINAL CORD**

The spinal cord lies within the vertebral column, in the upper two-thirds of the vertebral canal, and is continuous rostrally with the medulla oblongata of the brain stem (Ch. 43). For the most part, the spinal cord receives afferent input from, and controls the functions of, the trunk and limbs. Afferent and efferent connections between the periphery and the spinal cord travel in 31 pairs of segmentally arranged spinal nerves that attach to the cord as a linear series of dorsal and ventral rootlets. Adjacent groups of rootlets unite to form dorsal and ventral roots that combine to form the spinal nerves proper (Fig. 15.4). The dorsal and ventral roots are functionally distinct. Dorsal roots carry primary afferent nerve fibres from neuronal cell bodies located in dorsal root ganglia, whereas ventral roots carry efferent fibres from neuronal cell bodies located in the spinal grey matter.
Internally, the spinal cord consists of a central core of grey matter surrounded by white matter. The grey matter is configured in a characteristic H, or butterfly, shape that has projections known as dorsal and ventral horns (Fig. 15.5). In general, neurones situated in the dorsal horn are primarily concerned with sensory functions whilst those in the ventral horn are mostly associated with motor activities. At certain levels of the spinal cord a small lateral horn is additionally present, marking the location of the cell bodies of preganglionic sympathetic neurones. The central canal, a vestigial component of the ventricular system, lies at the centre of the spinal grey matter and runs the length of the cord. The white matter of the spinal cord consists of ascending and descending tracts that link spinal cord segments to one another and the spinal cord to the brain.
Fig. 15.5 Transverse section through the spinal cord at lumbar level. The section has been stained for nerve fibres, leaving the grey matter relatively unstained. (Figure enhanced by B. Crossman.)
The brain (encephalon) lies within the cranium (Ch. 26). The brain receives information from, and controls the activities of, the trunk and limbs mainly through connections with the spinal cord. It also possesses 12 pairs of cranial nerves through which it communicates mostly with structures of the head and neck. The brain is divided into major regions on the basis of ontogenetic growth and phylogenetic principles (Fig. 15.6, Fig. 15.7, Fig. 15.8). Ascending in sequence from the spinal cord, the principal divisions are the rhombencephalon or hindbrain, the mesencephalon or midbrain, and the prosencephalon or forebrain.

Fig. 15.6 Nomenclature and arrangement of the major divisions of the brain. A. The major features of the basic brain plan, including their relationships to the major special sensory organs of the head. B. The corresponding regions in the adult brain, seen in sagittal section. C, the organization of the ventricular system in the brain.
Fig. 15.7 Base of the brain, showing major divisions and cranial nerves. 
(Figure enhanced by B Crossman, from a photograph by Kevin Fitzpatrick on behalf of GKT School of Medicine, London.)
The rhombencephalon is subdivided into the myelencephalon or medulla oblongata, metencephalon or pons, and the cerebellum. The medulla oblongata, pons and midbrain are collectively referred to as the brain stem which lies upon the basal portions of the occipital and sphenoid bones (clivus). The medulla oblongata is the most caudal part of the brain stem and is continuous with the spinal cord below the level of the foramen magnum. The pons lies rostral to the medulla and is distinguished by a mass of transverse nerve fibres which connect it to the cerebellum. The midbrain is a short segment of brain stem, rostral to the pons. The cerebellum consists of paired hemispheres united by a median vermis and lies within the posterior cranial fossa, dorsal to the pons, medulla and caudal midbrain, with all of which it has numerous fibre connections.

The prosencephalon is subdivided into the diencephalon and the telencephalon. The diencephalon equates mostly to the thalamus and hypothalamus, but also includes the smaller epithalamus and subthalamus. The telencephalon is mainly composed of the two cerebral hemispheres or cerebrum. The diencephalon is almost completely embedded in the cerebrum and is therefore largely hidden from the exterior. The human cerebrum constitutes the major part of the brain. It occupies the anterior and middle cranial fossae and is directly related to the cranial vault. It consists of two cerebral hemispheres. The surface of each hemisphere is convoluted into a complex pattern of ridges (gyri) and furrows (sulci). Internally, each hemisphere has an outer layer of grey matter, the cerebral cortex, beneath which lies a thick mass of white matter (Fig. 15.9). One of the most important components of the cerebral white matter, the internal capsule (see Fig. 15.11), contains nerve fibres which pass to and from the cerebral cortex and lower levels of the neuraxis. Several large nuclei of grey matter, usually referred to as the basal ganglia, are partly embedded in the subcortical white matter. Connections between corresponding areas of the two sides of the brain cross the midline within commissures. By far the largest commissure is the corpus callosum, which links corresponding regions of the two cerebral hemispheres.
Fig. 15.9  Section through the cerebral hemisphere and brain stem showing the disposition of grey and white matter, the basal ganglia and the internal capsule.

(Photograph by Kevin Fitzpatrick on behalf of GKT School of Medicine, London.)
During prenatal development, the walls of the neural tube thicken greatly, but never completely obliterate the central lumen. Although the latter remains in the spinal cord as the narrow central canal, it becomes greatly expanded in the brain to form a series of interconnected cavities called the ventricular system (Ch. 16). In two regions, the fore- and hindbrains, parts of the roof of the neural tube do not generate nerve cells but become thin, folded sheets of highly vascular secretory tissue, the choroid plexuses. These secrete cerebrospinal fluid which fills the ventricles. The cavity of the rhombencephalon becomes expanded to form the fourth ventricle, which lies dorsal to the pons and upper half of the medulla. Caudally, the fourth ventricle is continuous with a canal in the caudal medulla and, through this, with the central canal of the spinal cord. The fourth ventricle is continuous with the subarachnoid space through three openings in its roof (the foramina of Luschka and of Magendie). At its rostral
extent, the fourth ventricle is continuous with a narrow channel, the cerebral aqueduct, which passes through the midbrain. The rostral end of the cerebral aqueduct opens out into the third ventricle, a narrow, slit-like, midline cavity which is bounded laterally by the diencephalon. At the rostral end of the third ventricle, a small aperture on each side leads into the large lateral ventricle which is located within each cerebral hemisphere (see Fig. 15.6C).
OVERVIEW OF ASCENDING SENSORY PATHWAYS

Sensory modalities are conventionally described as being either special senses or general senses. The special senses are olfaction, vision, taste, hearing and vestibular function. Afferent information is encoded by highly specialized sense organs and transmitted to the brain in cranial nerves I, II, VII, VIII and IX (Ch. 25).

The general senses include touch, pressure, vibration, pain, thermal sensation and proprioception (perception of posture and movement). Stimuli from the external and internal environments activate a diverse range of receptors in the skin, viscera, muscles, tendons and joints (Ch. 3). Afferent impulses from the trunk and limbs are conveyed to the spinal cord in spinal nerves whilst those from the head are carried to the brain in cranial nerves. The detailed anatomy of the complex pathways by which the various general senses impinge upon conscious levels is better understood by reference to certain common organizational principles. Whilst undoubtedly oversimplified and subject to exceptions, this schema is helpful in emphasizing the essential similarities that exist between the ascending sensory systems.

In essence, ascending sensory projections related to the general senses consist of a sequence of three neurones that extends from peripheral receptor to contralateral cerebral cortex (Fig. 15.10). These are often referred to as either primary, secondary and tertiary neurones or first-, second- and third-order neurones. Primary afferents have peripherally located sensory endings and cell bodies that lie in dorsal root ganglia or the sensory ganglia associated with certain of the cranial nerves. Their axons enter the CNS through spinal or trigeminal nerves and terminate by synapsing on the cell bodies of ipsilateral second-order neurones: the precise location of this termination depends upon the modality.
Primary afferent fibres carrying pain, temperature and coarse touch/pressure information from the trunk and limbs terminate in the dorsal horn of the spinal grey matter, near their point of entry into the spinal cord. Homologous fibres from the head terminate in the trigeminal sensory nucleus of the brain stem. The cell bodies of second-order neurones are located in either the dorsal horn or the trigeminal sensory nucleus. Their axons decussate and ascend to
the ventral posterior nucleus of the contralateral thalamus as the spinothalamic or the trigeminothalamic tract, respectively; they synapse on the cell bodies of third-order neurones in the thalamus. Axons of third-order neurones pass through the internal capsule to reach the cerebral cortex, terminating in the postcentral gyrus of the parietal lobe, which is also known as the primary somatosensory cortex.

Primary afferent fibres carrying proprioceptive information and fine (discriminative) touch from the trunk and limbs ascend ipsilaterally in the spinal cord as the dorsal columns (fasciculus gracilis and fasciculus cuneatus): they end by synapsing on second-order neurones in the dorsal column nuclei (nucleus gracilis and nucleus cuneatus) of the medulla. Axons of second-order neurones decussate in the medulla and then ascend as the medial lemniscus to the ventral posterior nucleus of the contralateral thalamus, where they synapse on the cell bodies of third-order neurones. Axons of third-order neurones pass through the internal capsule to reach the cerebral cortex, terminating in the primary somatosensory cortex. A similar homologous projection exists for afferents derived from the head.
OVERVIEW OF DESCENDING MOTOR PATHWAYS

Corticofugal fibres descend through the internal capsule and pass into the brain stem, where some of them (corticobulbar fibres) terminate. Corticobulbar fibres control the activity of brain stem neurones, including motor neurones within the cranial nerve nuclei. Current neuroanatomical nomenclature does not include a generally accepted term that denotes projections from the cerebral cortex to the brain stem as a whole. Such a term is, however, required in order to draw clinical comparison between the corticospinal system, coursing through the pyramids, and the functionally homologous fibres that terminate in the brain stem. The term ‘corticonuclear’ is sometimes used, but this implies specific innervation of cranial nerve nuclei and ignores the fact that numerous cortical efferents project to other sites, such as the reticular formation. The term ‘corticobulbar’ is also sometimes used but this, strictly speaking, refers to projections to the ‘bulb’, an archaic term for the medulla oblongata. In this text, ‘corticobulbar’ is used to denote cortical projections to the brain stem as a whole.

Corticospinal fibres (pyramidal tract) originate from widespread regions of the cerebral cortex, including the primary motor cortex of the frontal lobe where the opposite half of the body is represented in a detailed somatotopic fashion. They descend throughout the length of the brain stem; the majority cross to the contralateral side in the decussation of the pyramids in the medulla, subsequently continuing caudally as the lateral corticospinal tract of the spinal cord which terminates in association with interneurones and motor neurones of the spinal grey matter (Fig. 15.11). The principal function of the corticospinal and corticobulbar tracts is the control of fine, fractionated movements, particularly of those parts of the body where delicate muscular control is required. These tracts are particularly important in speech (corticobulbar tract) and movement of the hand (corticospinal tract).

The concept of upper and lower motor neurones is fundamental to the clinical description of the effects of lesions of the motor system. The signs and symptoms of upper and lower motor neurone lesions are very different and are indicative of the anatomical site of the lesion. ‘Lower motor neurones’ are the alpha motor neurones that innervate the extrafusal muscle fibres of skeletal muscle. In theory, the term ‘upper motor neurones’ refers collectively to all the descending pathways that impinge upon the activity of lower motor neurones. In common parlance, however, the term is often equated with the corticospinal tract. The terms upper and lower motor neurone lesion are used clinically to distinguish, for example, between the effects of a stroke in the internal capsule (a typical upper motor neurone lesion) and those of motor neurone disease (a typical lower motor neurone lesion).

Lower motor neurone lesions cause paralysis or paresis of specific muscles because they have lost their direct innervation. There is also loss or reduction
of tendon reflex activity and reduced muscle tone. Spontaneous muscular contractions (fasciculation) occur and affected muscles atrophy over time. Upper motor neurone lesions cause paralysis or paresis of movements as a result of loss of higher control. There is increased tendon reflex activity and increased muscle tone but no muscle atrophy occurs. A positive plantar (Babinski) reflex is present. The combination of paralysis, increased tendon reflex activity and hypertonia is referred to as spasticity.

The pathophysiology underlying the symptoms of upper motor neurone lesions is complex. This is because many descending pathways other than the corticospinal tract exist and they also influence lower motor neurone activity. These pathways include corticofugal projections to the brain stem (e.g. corticoreticular and corticopontine) that traverse the internal capsule and numerous pathways that originate within the brain stem itself (e.g. reticulospinal, vestibulospinal). Clearly, these pathways may be compromised to varying extents, depending upon the site of a lesion. Their involvement is believed to be important in the pathophysiological mechanisms that underlie the generation of spasticity. Pure corticospinal tract lesions, which are exceedingly rare in man because corticospinal tract fibres lie in close relationship to other pathways throughout most of their course, are believed specifically to cause deficits in delicate, fractionated movements and to induce the positive plantar reflex.

Two other major systems that contribute to the control of movement are the basal ganglia and the cerebellum. The basal ganglia are a group of large subcortical nuclei, the major components being the caudate nucleus, putamen and globus pallidus (Fig. 15.9; Ch. 22). These structures have important connections with the cerebral cortex, certain nuclei of the thalamus and subthalamus and with the brain stem. They appear to be involved in the selection of appropriate movements and the suppression of inappropriate ones. Disorders of the basal ganglia cause either too little movement (akinesia) or abnormal involuntary movements (dyskinesias) as well as tremor and abnormalities of muscle tone. The basal ganglia are sometimes described as being part of the so-called ‘extrapyramidal (motor) system'. This term is used to distinguish between the effects of basal ganglia disease and those of damage to the ‘pyramidal’ (corticospinal) system. However, the progressive elucidation of the anatomy of the basal ganglia and of the pathophysiology of motor disorders has revealed the close functional interrelationship between the two ‘systems’, and has rendered the terms that distinguish them largely obsolete (Brodal 1981). The cerebellum (Ch. 20) has rich connections with the brain stem, particularly the reticular and vestibular nuclei, and with the thalamus. It is concerned with the coordination of movement: cerebellar disorders cause ataxia, intention tremor and hypotonia.
PERIPHERAL NERVOUS SYSTEM

The PNS is composed mainly of spinal nerves, cranial nerves, their ganglia and their ramifications which carry afferent and efferent neurones between the CNS and the rest of the body. It also includes the peripheral part of the autonomic nervous system, notably the sympathetic trunks and ganglia, and the enteric nervous system which is composed of plexuses of nerve fibres and cell bodies in the wall of the alimentary tract.

SPINAL NERVES

Spinal nerves are the means by which the CNS receives information from, and controls the activities of, the trunk and limbs. Spinal nerves are considered in detail elsewhere on a regional basis (Sections 5, 6, 8 and 9).

In brief, there are 31 pairs of spinal nerves (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, 1 coccygeal) which contain a mixture of sensory and motor fibres. They originate from the spinal cord as continuous series of dorsal and ventral nerve rootlets. Adjacent groups of rootlets fuse to form dorsal and ventral roots which then merge to form the spinal nerves proper. The dorsal roots of spinal nerves contain afferent nerve fibres from cell bodies located in dorsal root ganglia. These cells give off both centrally and peripherally directed processes and do not have synapses on their cell bodies. The ventral roots of spinal nerves contain efferent fibres from cell bodies located in the spinal grey matter. They include motor neurones innervating skeletal muscle and preganglionic autonomic neurones.

Spinal nerves exit from the vertebral canal via their corresponding intervertebral foramina. They then divide to form a large ventral (anterior) ramus and a smaller dorsal (posterior) ramus. In general terms, the ventral ramus innervates the limbs together with the muscles and skin of the anterior part of the trunk. The dorsal ramus innervates the post-vertebral muscles and the skin of the back. The nerve fibres within the ventral rami serving the upper and lower limbs are redistributed within brachial and lumbosacral plexuses, respectively.
CRANIAL NERVES

Cranial nerves are the means by which the brain receives information from, and controls the activities of, the head and neck and to a lesser extent the thoracic and abdominal viscera. The component fibres, their route of exit from the cranial cavity, their subsequent peripheral course and the distribution and functions of the cranial nerves, are considered in detail elsewhere on a regional basis (Sections 4, 7, 8). Their origins, destinations and connections within the CNS are considered in this section.

Briefly, there are 12 pairs of cranial nerves. They are individually named and numbered (Roman numerals) in a rostrocaudal sequence (Table 15.1). Unlike spinal nerves, only some cranial nerves are mixed in function, carrying both sensory and motor fibres. Others are purely sensory or purely motor. The first cranial nerve (I; olfactory) has an ancient lineage and is derived from the forerunner of the cerebral hemisphere. It retains this unique position through the connections of the olfactory bulb, and is the only sensory cranial nerve that projects directly to the cerebral cortex rather than indirectly via the thalamus. The areas of cerebral cortex receiving olfactory input have a primitive cellular organization and are an integral part of the limbic system, which is concerned with the emotional aspects of behaviour (Ch. 23). The second cranial nerve (II; optic) consists of the axons of second order visual neurones and these terminate in the thalamus. The other ten pairs of cranial nerves attach to the brain stem and most of their component fibres originate from, or terminate in, the cranial nerve nuclei of the brain stem (Ch. 19).

- Somatic efferent
- General visceral efferent
- Branchial (special visceral) efferent

The sensory fibres in individual spinal and cranial nerves have characteristic, but often overlapping, peripheral distributions. As far as the innervation of the body surface is concerned, the area that is supplied by a particular spinal or cranial nerve is referred to as a dermatome. There is marked overlap between dermatomes of adjacent spinal nerves, particularly for the segments least affected by development of the limbs, i.e. the second thoracic to the first lumbar. In some regions, e.g. the upper anterior thoracic wall, the cutaneous nerves that supply adjoining areas are not from consecutive spinal nerves and the overlap is minimal. Maps of dermatome distribution are useful in clinical neurology to identify the location of pathology in patients with peripheral sensory deficits. Dermatome maps are somewhat inconsistently reported by different authors, reflecting the fact that the maps are composite constructs that have been compiled to a large extent by clinical observations on patients with cranial or spinal nerve pathology (Fig. 15.12). Detailed dermatome maps are described on a regional basis (Chs 42, 45, 79). The motor axons of individual spinal and cranial nerves tend to innervate anatomically and functionally related groups of skeletal muscles, that are referred to as myotomes.
AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system represents the visceral component of the nervous system. It consists of neurones located within both the CNS and PNS which are concerned with the control of the internal environment, through the innervation of secretory glands, cardiac and smooth muscle. Its functions are, however, closely integrated with those of the somatic nervous system.

Visceral afferent pathways in many ways resemble somatic afferent pathways. The peripheral processes of visceral afferents run through autonomic ganglia or plexuses, and possibly through somatic nerves. Their cell bodies of origin are unipolar neurones located in either cranial sensory or dorsal root ganglia. Their central processes accompany somatic afferent fibres through cranial nerves or dorsal spinal roots into the CNS where they establish connections that mediate autonomic reflexes and visceral sensation.

Visceral efferent pathways differ from their somatic equivalents in that the former are interrupted by peripheral synapses, there being a sequence of at least two neurones between the CNS and the target structure (Fig. 15.13). These are referred to as preganglionic and postganglionic neurones, respectively. The somata of preganglionic neurones are located in the visceral efferent nuclei of the brain stem and in the lateral grey columns of the spinal cord. Their axons, which are usually finely myelinated, exit from the CNS in certain cranial and spinal nerves and then pass to peripheral ganglia, where they synapse with postganglionic neurones. The axons of postganglionic neurones are usually unmyelinated. Postganglionic neurones are more numerous than preganglionic ones; one preganglionic neurone may synapse with 15 to 20 postganglionic neurones, which permits the wide distribution of many autonomic effects.
The autonomic nervous system is divided into three major parts: sympathetic, parasympathetic and enteric. These differ in organization and structure but are functionally integrated. Most, but not all, structures innervated by the autonomic nervous system receive both sympathetic and parasympathetic fibres, whereas the enteric nervous system is a network of neurones intrinsic to the wall of the gastrointestinal tract.

Two long-held dogmas are that the sympathetic and parasympathetic nervous systems are functionally antagonistic (because activation of their respective efferents has opposing actions upon target structures) and that sympathetic reactions are mass responses whereas parasympathetic reactions are usually more localized. A better concept is that the two sets of neurones constitute an integrated system for the
coordinated neural regulation of visceral and homeostatic functions. Moreover, even though widespread activation of the sympathetic nervous system may occur, e.g. in association with fear or rage, it is recognized that the sympathetic nervous system is also capable of discrete activation. In general, sympathetic activity results in the constriction of cutaneous arteries (increasing blood supply to the heart, muscles and brain), cardiac acceleration, an increase in blood pressure, contraction of sphincters and depression of peristalsis, all of which mobilize body energy stores for dealing with increased activity. Parasympathetic activity results in cardiac slowing and an increase in intestinal glandular and peristaltic activities, which may be considered to conserve body energy stores.

Autonomic activity is not initiated or controlled solely by the reflex connections of general visceral afferent pathways, nor do impulses in these pathways necessarily activate general visceral efferents. For example, in many situations demanding general sympathetic activity the initiator is somatic and typically arises either from the special senses or the skin. Rises in blood pressure and pupillodilatation may result from the stimulation of somatic receptors in the skin and other tissues. Peripheral autonomic activity is integrated at higher levels in the brain stem and cerebrum, including various nuclei of the brain stem reticular formation, thalamus and hypothalamus, the limbic lobe and prefrontal neocortex, together with the ascending and descending pathways which interconnect these regions.

The classical concept of autonomic neurotransmission is that preganglionic neurones of both sympathetic and parasympathetic systems are cholinergic and that postganglionic parasympathetic neurones are also cholinergic while those of the sympathetic nervous system are noradrenergic. The discovery of neurones that do not use either acetylcholine or noradrenaline (norepinephrine) as their primary transmitter, and the recognition of a multiplicity of substances in autonomic nerves which fulfil the criteria for a neurotransmitter or neuromodulator, have greatly complicated neuropharmacological concepts of the autonomic nervous system. Thus, adenosine 5'-triphosphate (ATP), numerous peptides and nitric oxide have all been implicated in the mechanisms of cell signalling in the autonomic nervous system. The principal cotransmitters in sympathetic nerves are ATP and neuropeptide Y, in parasympathetic nerves vasoactive intestinal polypeptide (VIP) and in enteric nerves ATP, VIP and substance P.

**SYMPATHETIC NERVOUS SYSTEM**

The sympathetic trunks are two ganglionated nerve cords that extend on either side of the vertebral column from the cranial base to the coccyx (Ch. 55). The ganglia are joined to spinal nerves by short connecting nerves called white and grey rami communicantes. Preganglionic axons join the trunk through the white rami communicantes while postganglionic axons leave the trunk in the grey rami. In the neck each sympathetic trunk lies posterior to the carotid sheath and anterior to the transverse processes of the cervical vertebrae. In the thorax the trunks are anterior to the heads of the ribs, in the abdomen they lie anterolateral to the bodies of the lumbar vertebrae, and in the pelvis they are anterior to the sacrum and medial to the anterior sacral foramina. Anterior to the coccyx the two trunks meet in a single, median, terminal ganglion. Cervical sympathetic ganglia are usually reduced to three by fusion. The internal carotid nerve, a continuation of the sympathetic trunk, issues from the cranial pole of the superior ganglion and accompanies the internal carotid artery.
through its canal into the cranial cavity. There are from 10 to 12 (usually 11) thoracic ganglia, 4 lumbar ganglia and 4 or 5 ganglia in the sacral region.

The cell bodies of preganglionic sympathetic neurones are located in the lateral horn of the spinal grey matter of all thoracic segments and the upper two or three lumbar segments (Fig. 15.14). Their axons are myelinated with diameters of 1.5–4 µm. They leave the cord in the corresponding ventral nerve roots and pass into the spinal nerves, but soon leave in white rami communicantes to join the sympathetic trunk (Fig. 15.15). Neurones like those in the lateral grey column exist at other levels of the cord above and below the thoracolumbar outflow and small numbers of their fibres leave in other ventral roots. Preganglionic sympathetic neurones release acetylcholine as their principal neurotransmitter.
Fig. 15.14 Transverse section through the thoracic spinal cord showing the lateral horn where preganglionic sympathetic neurones are located. (Figure enhanced by B Crossman.)
On reaching the sympathetic trunk, preganglionic fibres behave in one of several ways (Fig. 15.15). They may synapse with neurones in the nearest ganglion, or traverse the nearest ganglion and ascend or descend in the sympathetic chain to end in another ganglion. A preganglionic fibre may terminate in a single ganglion or, through collateral branches, synapse with neurones in several ganglia. Preganglionic fibres may traverse the nearest ganglion, ascend or descend and, without synapsing, emerge in one of the medially directed branches of the sympathetic trunk to synapse in the ganglia of autonomic plexuses (mainly situated in the midline, e.g. around the coeliac and mesenteric arteries). More than one preganglionic fibre may synapse with a single postganglionic neurone. Uniquely, the suprarenal gland is innervated directly by preganglionic sympathetic neurones that traverse the sympathetic trunk and coeliac ganglion without synapse.

The somata of sympathetic postganglionic neurones are located mostly in ganglia of the sympathetic trunk or ganglia in more peripheral plexuses. The axons of postganglionic neurones are, therefore, generally longer than those of preganglionic neurones, an exception being some of those that innervate pelvic viscera. The axons of ganglionic cells are unmyelinated. They are distributed to target organs in various ways. Those from a ganglion of the sympathetic trunk may return to the spinal nerve of preganglionic origin through a grey ramus communicans, which usually joins the nerve just proximal to the white ramus, and are then distributed through ventral and dorsal spinal rami to blood vessels, sweat glands, hairs, etc., in their zone of supply. Segmental areas vary in extent and overlap considerably. The extent of innervation of different effector systems, e.g. vasomotor, sudomotor, etc., by a particular nerve may not be the same. Alternatively, postganglionic fibres may pass in a medial branch of a ganglion direct to particular viscera, or innervate adjacent blood vessels, or pass along them externally to their peripheral distribution. They may ascend or descend before leaving the sympathetic trunk as described above. Many fibres are distributed along arteries and ducts as plexuses to distant effectors.

The principal neurotransmitter released by postganglionic sympathetic neurones is noradrenaline. The sympathetic system has a much wider distribution than the parasym pathetic. It innervates all sweat glands, the arrector pili muscles, the muscular walls of many blood vessels, the heart, lungs and respiratory tree, the abdominopelvic viscera, the oesophagus, the muscles of the iris, and the non-striated muscle of the urogenital tract, eyelids and elsewhere.

Postganglionic sympathetic fibres that return to the spinal nerves are vasoconstrictor to blood vessels, secretomotor to sweat glands and motor to the arrector pili muscles within their dermatomes. Those that accompany the motor nerves to voluntary muscles are probably only dilatatory. Most, if not all, peripheral nerves contain postganglionic sympathetic fibres. Those reaching the viscera are concerned with general vasoconstriction, bronchial and bronchiolar dilatation, modification of glandular secretion, pupillary dilatation, inhibition of alimentary muscle contraction, etc. A single preganglionic fibre probably synapses with the postganglionic neurones in only one effector system, which means that effects such as sudomotor and vasomotor actions can be separate.
PARASYMPATHETIC NERVOUS SYSTEM

Preganglionic parasympathetic neurone cell bodies are located in certain cranial nerve nuclei of the brain stem (see Fig. 19.1) and in the grey matter of the second to fourth sacral segments of the spinal cord. Efferent fibres, which are myelinated, emerge from the CNS only in cranial nerves III, VII, IX and X and in the second to fourth sacral spinal nerves. Preganglionic parasympathetic neurones are cholinergic.

The cell bodies of postganglionic parasympathetic neurones are mostly sited distant from the CNS, either in discrete ganglia located near the structures innervated, or dispersed in the walls of viscera. In the cranial part of the parasympathetic system there are four small peripheral ganglia, ciliary, pterygopalatine, submandibular and otic, that are all described on a regional basis in Section 4. These are solely efferent parasympathetic ganglia, unlike the trigeminal, facial, glossopharyngeal and vagal ganglia, all of which are concerned exclusively with afferent impulses and contain the cell bodies of sensory neurones. The cranial parasympathetic ganglia are also traversed by afferent fibres, postganglionic sympathetic fibres, and, in the case of the otic ganglion, even by branchial efferent fibres; none of these fibres synapse in the ganglia. Postganglionic parasympathetic fibres are usually unmyelinated and shorter than their counterparts in the sympathetic system, because the ganglia in which the parasympathetic fibres synapse are in or near the viscera they supply. Postganglionic parasympathetic neurones are cholinergic.
ENTERIC NERVOUS SYSTEM AND INTRINSIC NEURONES

Many peripheral autonomic ganglia contain neurones derived from the neural crest during embryonic development that are anatomically distinct from classical sympathetic and parasympathetic neurones. Connections between these intrinsic neurones allow them to sustain and modulate visceral activities by local reflex mechanisms. The enteric nervous system consists of many millions of neurones and enteric glial cells grouped into ganglionated plexuses lying in the wall of the gastrointestinal tract: ganglia containing neuronal cell bodies and glia are connected by bundles of axons to form myenteric and submucous plexi that extend from the oesophagus to the anal sphincter (Chs 3 and 60). This intrinsic circuitry mediates numerous reflex functions including the contractions of the muscular coats of the alimentary tract, secretion of gastric acid, intestinal transport of water and electrolytes and the regulation of mucosal blood flow. Although complex interactions occur between the enteric and sympathetic and parasympathetic nervous systems, the enteric nervous system is capable of sustaining local reflex activity independent of the CNS.

Since intrinsic neurones survive after section of the extrinsic sympathetic and parasympathetic nerves, organs that are transplanted are not truly denervated. Separation from their autonomic input often has no obvious impact on the non-striated muscle or glands innervated by autonomic fibres: contraction may be unaffected and no structural changes ensue. This has been variously attributed to the continued activity of local plexuses or to the intrinsic activity of visceral muscle. In some important instances, however, denervation does result in cessation of activity, e.g. in sweat glands, pilomotor muscle, orbital non-striated muscle and the suprarenal medulla.
VISCERAL AFFERENT PATHWAYS

General visceral afferent fibres from the viscera and blood vessels accompany their efferent counterparts, and are the peripheral processes of unipolar cell bodies located in some cranial nerve and dorsal root ganglia. They are contained in the vagus, glossopharyngeal, and possibly other cranial nerves; the second to fourth sacral spinal nerves, distributed with the pelvic splanchnic nerves; and in thoracic and upper lumbar spinal nerves, distributed through rami communicantes and alongside the efferent sympathetic innervation of viscera and blood vessels.

The cell bodies of vagal general visceral afferent fibres are in the superior and inferior vagal ganglia. Their peripheral processes are distributed to terminals in the pharyngeal and oesophageal walls where, acting synergistically with glossopharyngeal visceral afferents in the pharynx, they are concerned with swallowing reflexes. Vagal afferents are also believed to innervate the thyroid and parathyroid glands. In the heart, vagal afferents innervate the walls of the great vessels, the aortic bodies and pressor receptors, where they are stimulated by raised intravascular pressure. In the lungs they are distributed via the pulmonary plexuses. They supply bronchial mucosa, where they are probably involved in cough reflexes; bronchial muscle, where they encircle myocytes and end in tendrils, which are sometimes regarded as muscle spindles and which are believed to be stimulated by change in the length of myocytes; interalveolar connective tissue, where their knob-like endings, together with terminals on myocytes, may evoke Hering–Breuer reflexes; the adventitia of pulmonary arteries, where they may be pressor receptors; and the intima of pulmonary veins, where they may be chemoreceptors. Vagal visceral afferent fibres also end in the gastric and intestinal walls, digestive glands, and the kidneys. Fibres ending in the gut and its ducts respond to stretch or contraction. Gastric impulses may evoke sensations of hunger and nausea.

The cell bodies of glossopharyngeal general visceral afferents are in the glossopharyngeal ganglia. Their peripheral processes innervate the posterior lingual region, the tonsils and pharynx, but they do not innervate taste buds. They also innervate the carotid sinus and the carotid body, which contain receptors sensitive to tension and changes in chemical composition of the blood. Impulses from these receptors are essential to circulatory and respiratory reflexes.

Visceral afferents that enter the spinal cord through spinal nerve roots terminate in the spinal grey matter. The central processes of vagal and glossopharyngeal afferent fibres end in the vagal nucleus or the nucleus solitarius of the medulla. Visceral afferents establish connections within the CNS that mediate autonomic reflexes. In addition, afferent impulses probably mediate visceral sensations such as hunger, nausea, sexual excitement,
vesical distension, etc. Visceral pain fibres may follow these routes. Although viscera are insensitive to cutting, crushing or burning, excessive tension in smooth muscle and some pathological conditions produce visceral pain. In visceral disease, vague pain may be felt near the viscus itself (visceral pain) or in a cutaneous area or other tissue whose somatic afferents enter spinal segments receiving afferents from the viscus, a phenomenon known as referred pain. If inflammation spreads from a diseased viscus to the adjacent parietal serosa (e.g. the peritoneum), somatic afferents will be stimulated, causing local somatic pain, which is commonly spasmodic. Referred pain is often associated with local cutaneous tenderness.

Afferent fibres in pelvic splanchnic nerves innervate pelvic viscera and the distal part of the colon. Vesical receptors are widespread: those in muscle strata are associated with thickly myelinated fibres and are believed to be stretch receptors, possibly activated by contraction. Pain fibres from the bladder and proximal urethra traverse both the pelvic splanchnic nerves and the inferior hypogastric plexus, hypogastric nerves, superior hypogastric plexus and lumbar splanchnic nerves to reach their cell bodies in ganglia on the lower thoracic and upper lumbar dorsal spinal roots: the significance of this dual sensory pathway is uncertain. Lesions of the cauda equina abolish pain from vesical overdistension, but hypogastric section is ineffective. Pain fibres from the uterus traverse the hypogastric plexus and lumbar splanchnic nerves to reach somata in the lowest thoracic and upper lumbar spinal ganglia, and hypogastric division may relieve dysmenorrhoea. Afferents from the uterine cervix traverse the pelvic splanchnic nerves to reach their somata in the upper sacral spinal ganglia: stretching the cervix uteri causes pain but cautery and biopsy excisions do not.

In general, afferent fibres that accompany pre- and postganglionic sympathetic fibres have a segmental arrangement and end in spinal cord segments from which preganglionic fibres innervate the region or viscus concerned. General visceral afferents entering thoracic and upper lumbar spinal segments are largely concerned with pain. Nociceptive impulses from the pharynx, oesophagus, stomach, intestines, kidneys, ureter, gallbladder and bile ducts seem to be carried in sympathetic pathways. Cardiac nociceptive impulses enter the spinal cord in the first to fifth thoracic spinal nerves, mainly via the middle and inferior cardiac nerves, but some fibres pass directly to the spinal nerves. It is said that there are no general visceral afferents in the superior cardiac nerves. Peripherally, the fibres pass through the cardiac plexuses and along the coronary arteries. Myocardial anoxia may evoke symptoms of angina pectoris in which pain is typically presternal, and is also referred to much of the left chest, and radiates to the left shoulder, the medial aspect of the left arm, along the left side of the neck to the jaw and occiput, and down to the epigastrium. Cardiac afferents carried in vagal cardiac branches are concerned with the reflex depression of cardiac activity. Ureteric pain fibres, also running with sympathetic fibres, are presumably
involved in the agonizing renal colic that follows obstruction by calculi. Afferent fibres from the testis and ovary run through the corresponding plexuses to somata in the tenth and eleventh thoracic dorsal root ganglia.

Certain primary afferent nerve fibres, that have their cell bodies in cranial and dorsal root ganglia, also have an efferent function (so-called sensory–motor nerves). The importance of sensory–motor nerve regulation in many organs, such as the gut, lungs, heart and blood vessels, is now recognized. While most such nerves are, presumably, purely sensory, certain of them have been termed sensory–motor because they release transmitters from their peripheral endings during the axon reflex and have a motor rather than a sensory role. The primary substances released in this way are substance P, calcitonin gene-related peptide (CGRP) and ATP. These act on target cells to produce several biological actions which include vasodilatation, increased venular permeability, changes in smooth muscle contractility, degranulation of mast cells and a variety of effects on leukocytes and fibroblasts, a process collectively known as ‘neurogenic inflammation’. The local release of such substances may play a trophic role in the maintenance of tissue integrity and repair in response to injury.
Paraganglia are extrasuprarenal aggregations of chromaffin tissue, distributed near to or within the autonomic nervous system (Fig. 15.16). Cells like those in paraganglia also occur in the sympathetic ganglia of various viscera and in a variety of retroperitoneal and mediastinal sites. All are derived from the neural crest, and all synthesize and store catecholamines. Their functions differ with location: some cells act as interneurones, others as sources of neuroendocrine secretion. Paraganglionic catecholamine release occurs mainly in response to chemical rather than to neural stimuli, e.g. in the suprarenal medulla. Extrasuprarenal chromaffin tissue is prominent in the fetus, and acts as the main source of catecholamines while the suprarenal medulla is immature. Although many paraganglia degenerate soon after birth, others persist into adulthood, often as microscopic paraganglia.
Fig. 15.16 The principal aggregations of ‘classic’ chromaffin tissue in the human neonate. The aggregates in stippled blue lie deep to overlying structures.

Paraganglia are well-vascularized and their secretory cells are usually close to one or more fenestrated capillaries. Most have a sympathetic innervation and act as endocrine organs, e.g. suprarenal medullary chromaffin cells. Others are associated with the parasympathetic system, and their secretions probably have activities on local nerve endings, e.g. the carotid body. Paraganglia produce regulatory peptides, particularly enkephalins, and store
them as cytoplasmic granules until stimulated to release them. Their secretions may exert a local paracrine action on nearby cells, in addition to having remote endocrine effects.

Description of sensory-motor nerves.

Unconventional but highly-readable text of neuroanatomy with a strong emphasis on clinical relevance. Contains particularly good account of motor pathways.

A review of neurotransmission in the autonomic nervous system.

Contains extensive material on the neurotransmitters of the autonomic nervous system.

CHAPTER 16 – Ventricular system and subarachnoid space

The cerebral ventricular system consists of a series of interconnecting spaces and channels within the brain (Fig. 16.1) which are derived from the central lumen of the embryonic neural tube and the cerebral vesicles to which it gives rise (Ch. 24). Each cerebral hemisphere contains a large lateral ventricle that communicates near its rostral end with the third ventricle via the interventricular foramen (foramen of Monro). The third ventricle is a midline, slit-like cavity lying between the right and left thalamus and hypothalamus. Caudally, the third ventricle is continuous with the cerebral aqueduct, a narrow tube that passes the length of the midbrain, and which is continuous in turn with the fourth ventricle, a wide tent-shaped cavity lying between the brain stem and cerebellum. The fourth ventricle communicates with the subarachnoid space of the cisterna magna though the foramen of Magendie, and of the cerebellopontine angle through the foramina of Luschka; caudally it is continuous with the vestigial central canal of the spinal cord.

The ventricular system contains cerebrospinal fluid (CSF), which is mostly secreted by the choroid plexuses located within the lateral, third and fourth ventricles. CSF flows from the lateral to the third ventricle, then through the cerebral aqueduct and into the fourth ventricle. It leaves the fourth ventricle through the foramen of Magendie and the foramina of Luschka to reach the subarachnoid space surrounding the brain.

TOPOGRAPHY AND RELATIONS OF THE VENTRICULAR SYSTEM

LATERAL VENTRICLE

Viewed from its lateral aspect, the lateral ventricle has a roughly C-shaped profile. The shape is a consequence of the developmental expansion of the frontal, parietal and occipital regions of the hemisphere, which displaces the temporal lobe inferiorly and...
anteriorly. Both the caudate nucleus and the fornix, which lie in the wall of the ventricle, have adopted a similar morphology, so that the tail of the caudate nucleus encircles the thalamus in a C-shape, and the fornix traces the outline of the ventricle forwards to the interventricular foramen.

The lateral ventricle is customarily divided into a body and anterior (frontal), posterior (occipital) and inferior (temporal) horns. The anterior horn lies within the frontal lobe. It is bounded anteriorly by the posterior aspect of the genu and rostrum of the corpus callosum, and its roof is formed by the anterior part of the body of the corpus callosum. The anterior horns of the two ventricles are separated by the septum pellucidum. The coronal profile of the anterior horn is roughly that of a flattened triangle in which the rounded head of the caudate nucleus forms the lateral wall and floor (Figs 16.2, 16.3). The anterior horn extends back as far as the interventricular foramen. The body lies within the frontal and parietal lobes and extends from the interventricular foramen to the splenium of the corpus callosum. The bodies of the lateral ventricles are separated by the septum pellucidum, which contains the columns of the fimbriae in its lower edge. The lateral wall of the body of the ventricle is formed by the caudate nucleus superiorly and the thalamus inferiorly. The boundary between the thalamus and caudate nucleus is marked by a groove (Fig. 16.2) which is occupied by a fascicle of nerve fibres, the stria terminalis, and by the thalamostriate vein (see Fig. 22.5). The inferior limit of the body of the ventricle and its medial wall are formed by the body of the fornix (Fig. 16.4). The fornix is separated from the thalamus by the choroidal fissure. The choroid plexus lies in the fornix and covers part of the thalamus and fornix. The body of the lateral ventricle widens posteriorly to become continuous with the posterior and inferior horns at the collateral trigone or atrium. The posterior horn curves posteromedially into the occipital lobe. It is usually diamond-shaped or square in outline, and the two sides are often asymmetrical. Fibres of the tapetum of the corpus callosum separate the ventricle from the optic radiation, and form the roof and lateral wall of the posterior horn. Fibres of the splenium of the corpus callosum (forceps major) pass medially as they sweep back into the occipital lobe, and produce a rounded elevation in the upper medial wall of the posterior horn. Lower down, a second elevation, the calcar avis, corresponds to the deeply infolded cortex of the anterior part of the calcarine sulcus. The inferior horn is the largest compartment of the lateral ventricle and extends forwards into the temporal lobe. It curves round the posterior aspect of the thalamus (pulvinar), passes downwards and posterolaterally and then curves anteriorly to end within 2.5 cm of the temporal pole, near the uncus. Its position relative to the surface of the hemisphere usually corresponds to the superior temporal sulcus. The roof of the inferior horn is formed mainly by the tapetum of the corpus callosum, but also by the tail of the caudate nucleus and the stria terminalis, which extend forwards in the roof to terminate in the amygdala at the anterior end of the ventricle. The floor of the ventricle consists of the hippocampus medially and the collateral eminence, formed by the infolding of the collateral sulcus, laterally. The inferior part of the choroid fissure lies between the fimbria (a distinct bundle of efferent fibres that leaves the hippocampus) and the stria terminalis in the roof of the temporal horn (Fig. 16.5). The temporal extension of the choroid plexus fills this fissure and covers the outer surface of the hippocampus.

THIRD VENTRICLE

The third ventricle is a midline, slit-like cavity which is derived from the primitive forebrain vesicle (Figs 16.1, 16.4, 16.6, 16.7; see Fig. 15.8). The upper part of the lateral wall of the ventricle is formed by the medial surface of the anterior two-thirds of the thalamus, and the lower part is formed by the hypothalamus anteriorly and the subthalamus posteriorly. An indistinct hypothalamic sulcus extends horizontally on the ventricular wall between the interventricular foramen and the cerebral aqueduct, and marks the boundary between the thalamus and hypothalamus. Dorsally, the lateral wall is limited by a ridge covering the stria medullaris thalami. The lateral walls of the third ventricle are joined by an interthalamic adhesion, or massa intermedia, a band of grey matter which extends from one thalamus to the other.

Fig. 16.6 Sagittal MRI scan of the head.
Anteriorly, the third ventricle extends to the lamina terminalis (Fig. 16.7). This thin structure stretches from the optic chiasma to the rostrum of the corpus callosum and represents the rostral boundary of the embryonic neural tube. The lamina terminalis forms the roof of the small virtual cavity lying immediately below the ventricle called the cistern of the lamina terminalis. This is important because it contains the anterior communicating artery and aneurysm formation at this site may cause intraventricular haemorrhage through the thin membrane of the lamina terminalis. Above this, the anterior wall is formed by the diverging columns of the fornices and the transversely orientated anterior commissure, which crosses the midline. The anterior and posterior commissures are important neuroradiological landmarks. Prior to the introduction of modern imaging techniques, the fact that these commissures could be identified by ventriculography led to their use as reference markers for stereotaxic surgical procedures. This convention is now universal: the positions of the anterior and posterior commissures are used as the basic reference points for surgical atlases of brain anatomy. The narrow interventricular foramen is located immediately posterior to the column of the fornix and separates the fornix from the anterior nucleus of the thalamus.

There is a small, angular, optic recess at the base of the lamina terminalis, just dorsal to and extending into the optic chiasma. Behind it, the anterior part of the floor of the third ventricle is formed mainly by hypothalamic structures. Immediately behind the optic chiasma lies the thin infundibular recess, which extends into the pituitary stalk. Behind this recess, the tuber cinereum and the mammillary bodies form the floor of the ventricle.

The roof of the third ventricle is a thin ependymal layer that extends from its lateral walls to the choroid plexus, which spans the choroidal fissure (Fig. 16.4). Above the
roof is the body of the fornix. The posterior boundary of the ventricle is marked by a suprapineal recess above the pineal gland, a pineal (epiphysial) recess, which extends into the pineal stalk, and by the posterior commissure. Below the commissure the ventricle is continuous with the cerebral aqueduct of the midbrain.
CEREBRAL AQUEDUCT

The cerebral aqueduct is a small tube, roughly circular in transverse section and 1–2 mm in diameter. It extends throughout the dorsal quarter of the midbrain in the midline and is surrounded by the periaqueductal (central) grey matter (Fig. 16.7; see Fig. 19.19). Rostrally, it commences immediately behind and below the posterior commissure, where it is continuous with the caudal aspect of the third ventricle. Caudally, it is continuous with the lumen of the fourth ventricle at the junction of the midbrain and pons. The superior and inferior colliculi are dorsal to the aqueduct and the midbrain tegmentum is ventral.
FOURTH VENTRICLE

The fourth ventricle lies between the brain stem and the cerebellum (Figs 16.1B, 16.6, 16.7, 16.8; see Fig. 19.3). Rostrally it is continuous with the cerebral aqueduct, and caudally with the central canal of the spinal cord. In sagittal section, the fourth ventricle has a characteristic triangular profile, and the apex of its tented roof protrudes into the inferior aspect of the cerebellum. The ventricle is at its widest at the level of the pontomedullary junction, where a lateral recess on both sides extends to the lateral border of the brain stem. At this point the lateral aperture of the fourth ventricle (foramen of Luschka) provides access to the subarachnoid space at the cerebellopontine angle; CSF flows through it into the lateral extension of the pontine cistern. Occasionally, a lateral recess may not open.

![Diagram of the fourth ventricle](image)

Fig. 16.8 The floor of the fourth ventricle, dorsal aspect of the brain stem.

The floor of the fourth ventricle is a shallow diamond-shaped, or rhomboidal, depression (rhomboid fossa) on the dorsal surfaces of the pons and the rostral half of the medulla. It consists largely of grey matter and contains important cranial nerve nuclei. The precise location of some nuclei is discernible from surface features. The superior part of the ventricular floor is triangular in shape and is limited laterally by the superior cerebellar peduncles as they converge towards the cerebral aqueduct. Its posterior limit is called the obex. The inferior part of the ventricular floor is also
triangular in shape and is bounded caudally by the gracile and cuneate tubercles, which contain the dorsal column nuclei, and, more rostrally, by the diverging inferior cerebellar peduncles. A longitudinal median sulcus divides the floor of the fourth ventricle. Each half is itself divided, by an often indistinct sulcus limitans, into a medial region known as the medial eminence and a lateral region known as the vestibular area. The vestibular nuclei lie beneath the vestibular area. In the superior part of the ventricular floor, the medial eminence is represented by the facial colliculus, a small elevation produced by an underlying loop of efferent fibres from the facial nucleus which covers the abducens nucleus. Between the facial colliculus and the vestibular area the sulcus limitans widens into a small depression, the superior fovea. In its upper part, the sulcus limitans constitutes the lateral limit of the floor of the fourth ventricle. Here, a small region of bluish-grey pigmentation denotes the presence of the subjacent locus coeruleus. Inferior to the facial colliculus, at the level of the lateral recess of the ventricle, a variable group of nerve fibre fascicles, known as the striae medullaris, runs transversely across the ventricular floor and passes into the median sulcus. In the inferior area of the floor of the fourth ventricle, the medial eminence is represented by the hypoglossal triangle (trigone), which lies over the hypoglossal nucleus. Laterally, the sulcus limitans widens to produce an indistinct inferior fovea. Caudal to the inferior fovea, between the hypoglossal triangle and the vestibular area, is the vagal triangle (trigone), which covers the dorsal motor nucleus of the vagus. The triangle is crossed below by a narrow translucent ridge, the funiculus separans, which is separated from the gracile tubercle by the small area postrema. The funiculus and area postrema are both covered by thickened ependyma, containing tanycytes; the area postrema also contains neurones. The blood–brain barrier is modified at both sites.

The roof of the fourth ventricle is formed by the superior and inferior medullary veli. Superiorly, a thin sheet of tissue, the superior medullary velum, stretches across the ventricle between the converging superior cerebellar peduncles (Fig. 16.8). The superior medullary velum is continuous with the cerebellar white matter and is covered dorsally by the lingula of the superior vermis. The inferior medullary velum is more complex and is mostly composed of a thin sheet, devoid of neural tissue, formed by ventricular ependyma and the pia mater of the tela choroidea, which covers it dorsally. A large median aperture (foramen of Magendie) is present in the roof of the ventricle as a perforation in the posterior medullary velum, just inferior to the nodule of the cerebellum: CSF flows through the foramen from the ventricle into the cisterna magna.
CIRCUMVENTRICULAR ORGANS

The walls of the ventricular system are lined with ependymal cells covering a subependymal layer of glia. At certain midline sites in the ventricular walls, collectively referred to as circumventricular organs, the blood–brain barrier is absent and specialized ependymal cells called tanycytes are present (Fig. 16.9). The functions of ependyma and tanycytes may include secretion into the CSF; transport of neurochemicals from subjacent neurones, glia or vessels to the CSF; transport of neurochemicals from the CSF to the same subjacent structures; chemoreception. In the adult, the ependymal and subependymal glial cell layers are the source of undifferentiated stem cells that are currently under intensive study for their potential neurorestorative properties.
The circumventricular organs include the vascular organ (organum vasculosum), subfornical organ, neurohypophysis, median eminence, subcommissural organ, pineal gland and area postrema.

The vascular organ lies in the lamina terminalis between the optic chiasma and the anterior commissure. Its external zone contains a richly fenestrated vascular plexus, which covers glia and a network of nerve fibres. The ependymal cells of the vascular organ, like those of other circumventricular organs, are flattened and have few cilia. The major inputs appear to come from the subfornical organ, locus coeruleus and a number of hypothalamic
nuclei; the vascular organ projects to the median preoptic and supraoptic nuclei. The vascular organ is involved in the regulation of fluid balance and may also have neuroendocrine functions.

The subfornical organ lies at the level of the interventricular foramen. It contains many neurones, glial cells and a dense fenestrated capillary plexus, and is covered by flattened ependyma. It is believed to have widespread hypothalamic interconnections and to function in the regulation of fluid balance and drinking.

The neurohypophysis (posterior pituitary) is the site of termination of neurosecretory projections from the supraoptic and paraventricular nuclei of the hypothalamus. Neurones in these nuclei release vasopressin and oxytocin respectively into the capillary bed of the neurohypophysis, where the hormones gain access to the general circulation.

The median eminence contains the terminations of axons of hypothalamic neurosecretory cells. Peptides released from these axons control the hormonal secretions of the anterior pituitary via the pituitary portal system of vessels.

The subcommissural organ lies ventral to and below the posterior commissure, near the inferior wall of the pineal recess. The ependymal cells on the dorsal aspect of the cerebral aqueduct are tall, columnar and ciliated, with granular basophilic cytoplasm: they may be involved in the secretion of materials into the CSF from adjoining axonal terminals or capillaries.

The pineal gland (see Ch. 21) is a small structure approximately 8 mm in diameter situated rostro-dorsal to the superior colliculus and behind the stria medullaris. It is part of the epithalamus and consists of internal lobules of pinealocytes and sparse neurones covered by a pial capsule. It secretes melatonin which appears to be involved in the inhibition of puberty in children and in the in the regulation of the sleep–wake cycle in both children and adults.

The area postrema is a bilaterally paired structure, located at the caudal limit of the floor of the fourth ventricle. It is an important chemoreceptive area that triggers vomiting in response to the presence of emetic substances in the blood. The area postrema, along with the nucleus of the solitary tract and the dorsal motor nucleus of the vagus, makes up the so-called dorsal vagal complex, which is the major termination site of vagal afferent nerve fibres.
CHOROID PLEXUS AND CEREBROSPINAL FLUID

CHOROID PLEXUS

The vascular pia mater in the roofs of the third and fourth ventricles, and in the medial wall of the lateral ventricle along the line of the choroid fissure, is closely apposed to the ependymal lining of the ventricles, without any intervening brain tissue. It forms the tela choroidea, which gives rise to the highly vascularized choroid plexuses from which CSF is secreted into the lateral, third and fourth ventricles (Figs 16.2, 16.4, 16.5). The body or stroma of the choroid plexus consists of many capillaries, separated from the subarachnoid space by the pia mater and choroid ependymal cells.

In the lateral ventricle, the choroid plexus extends anteriorly as far as the interventricular foramen, through which it is continuous across the third ventricle with the plexus of the opposite lateral ventricle. From the interventricular foramen, the plexus passes posteriorly, in contact with the thalamus, curving round its posterior aspect to enter the inferior horn of the ventricle and reach the hippocampus. Throughout the body of the ventricle, the choroid fissure lies between the fornix superiorly and the thalamus inferiorly (Fig. 16.4).

From above, the tela choroidea is triangular with a rounded apex between the interventricular foramina, often indented by the anterior columns of the fornices. Its lateral edges are irregular, and contain choroid vascular fringes. At the posterior basal angles of the tela, these fringes continue and curve on into the inferior horn of the ventricle. When the tela is removed, a transverse slit (the transverse fissure) is left between the splenium and the junction of the ventricular roof with the tectum. The transverse fissure contains the roots of the choroid plexus of the third ventricle and of the lateral ventricles.

The choroid plexus of the third ventricle is attached to the tela choroidea which is, in effect, the thin roof of the third ventricle as it develops during fetal life. In coronal sections of the cerebral hemispheres, the choroid plexus of the third ventricle can be seen in continuity with the choroid plexus of the lateral ventricles.

The choroid plexus of the fourth ventricle is similar in structure to that of the lateral and third ventricles. The roof of the inferior part of the fourth ventricle develops as a thin sheet in which the pia mater is in direct contact with the ependymal lining of the ventricle. This thin sheet, the tela choroidea of the fourth ventricle, lies between the cerebellum and the inferior part of the roof of the ventricle. The choroid plexus of the fourth ventricle is T-shaped, with vertical and horizontal limbs but the precise form varies widely from a single vertical limb to an elongated ‘T’ which extends out through the foramina of Luschka into the cerebellopontine angle. The vertical (longitudinal) limb is
double, flanks the midline and is adherent to the roof of the ventricle. The limbs fuse at the superior margin of the median aperture (foramen of Magendie) and are often prolonged on to the ventral aspect of the cerebellar vermis. The horizontal limbs of the plexus project into the lateral recesses of the ventricle. Small tufts of plexus pass through the lateral apertures (foramina of Luschka) and emerge, still covered by ependyma, in the subarachnoid space of the cerebellopontine angle.

The blood supply of the choroid plexus in the tela choroidea of the lateral and third ventricles is usually via a single vessel from the anterior choroidal branch of the internal carotid artery and several choroidal branches of the posterior cerebral artery; the two sets of vessels anastomose to some extent. Capillaries drain into a rich venous plexus served by a single choroidal vein. The blood supply of the fourth ventricular choroid plexus is from the inferior cerebellar arteries.
CEREBROSPINAL FLUID

CSF is a clear, colourless, liquid. In normal individuals CSF contains a very small amount of protein and differs from blood in its electrolyte content. It is not simply an ultrafiltrate of blood but is actively secreted by the choroid plexus epithelium. Choroid plexus epithelial cells have the characteristics of transport and secretory cells. Their apical surfaces, from which CSF is secreted, possess microvilli, and their basal surfaces exhibit interdigitations and folding. There are tight junctions at the apical ends of the epithelial cells, which are permeable to small molecular weight substances. Fenestrated capillaries in the stroma of the choroid plexus lie just beneath the epithelial cells. A blood–CSF barrier is sited at the choroid plexus epithelium.

Most of the CSF is secreted by the choroid plexuses in the lateral, third and fourth ventricles. However, there is also a small contribution from the ependymal lining of the ventricles and from the extracellular fluid from the brain parenchyma.
The subarachnoid space lies between the arachnoid and the pia mater. The cerebral subarachnoid space is connected with the fourth ventricle of the brain by three openings. The median aperture (foramen of Magendie) lies in the median plane in the inferior part of the roof of the fourth ventricle and provides communication with the cisterna magna. The paired lateral apertures (foramina of Luschka) are located at the ends of the lateral recesses of the fourth ventricle, and open into the subarachnoid space at the cerebellopontine angle, behind the upper roots of the glossopharyngeal nerves. The subarachnoid space therefore contains cerebrospinal fluid (CSF); it also contains the larger arteries and veins which traverse the surface of the brain (Fig. 16.10).

![Fig. 16.10](image)

The relationships between the dura, the leptomeninges and the blood vessels that enter and leave the cerebral cortex. The subarachnoid space is divided by trabeculae.

Trabeculae, in the form of sheets or fine filiform structures, traverse the subarachnoid space from the deep layers of the arachnoid mater to the pia mater and are also attached to large blood vessels within the subarachnoid space (Fig. 16.10). Each trabecula has a core of collagen and is coated by leptomeningeal cells. The trabeculae that cross the subarachnoid space may form compartments, particularly in
the perivascular regions, which may facilitate directional flow of CSF through the subarachnoid space.

Arteries and veins in the subarachnoid space are coated by a thin layer of leptomeninges, often only one cell thick. Cranial and spinal nerves that traverse the subarachnoid space to pass out of cranial or intervertebral foramina are coated by a thin layer of leptomeninges which fuses with the arachnoid at the exit foramina.

Arachnoid and pia mater are in close apposition over the convexities of the brain, such as the cortical gyri, whereas concavities are followed by the pia but spanned by the arachnoid. This arrangement produces a subarachnoid space of greatly variable depth that is location dependent. The more expansive spaces are identified as subarachnoid cisterns (Fig. 16.11), which are continuous with each other through the general subarachnoid space. Subarachnoid trabeculae that cross the subarachnoid cisterns are long and filamentous.
The largest cistern, the cisterna magna or cerebellomedullary cistern, is formed where the arachnoid bridges the interval between the medulla oblongata and the inferior surface of the cerebellum. The cistern is continuous above with the lumen of the fourth ventricle through its median aperture, the foramen of Magendie, and below with the subarachnoid space of the spinal cord. The pontine cistern is an extensive space ventral to the pons, that is continuous below with the spinal subarachnoid space, behind with the cisterna magna and, rostral to the pons, with the interpeduncular cistern. The basilar artery runs through the pontine cistern into the interpeduncular cistern. As the arachnoid mater spans between the two temporal lobes it is separated from the cerebral peduncles and structures within the interpeduncular fossa by the interpeduncular cistern, which contains the circulus arteriosus (circle of Willis). Anteriorly, the interpeduncular cistern extends to the optic chiasma. The cistern of the lateral fossa is formed by the arachnoid as it bridges the lateral sulcus between the frontal, parietal and temporal opercula; it contains the middle cerebral artery. The cistern of the great cerebral vein (cisterna ambiens or superior cistern) lies posterior to the brain stem and third ventricle, and occupies the interval between the splenium of the corpus callosum and the superior cerebellar surface. The great cerebral vein traverses this cistern and the pineal gland protrudes into it.

Several smaller cisterns have been described, including the prechiasmatic and postchiasmatic cisterns, which are related to the optic chiasma, and the cistern of the lamina terminalis and the supracallosal cistern, all of which are extensions of the interpeduncular cistern and contain the anterior cerebral arteries. The subarachnoid space also extends through the optic foramen into the orbit where it is bounded by the optic nerve sheath. The latter is formed by fusion of the arachnoid and dura mater, and surrounds the orbital portion of each optic nerve as far as the back of the globe, where the dura fuses with the sclera of the eye.
CIRCULATION OF CEREBROSPINAL FLUID

The total CSF volume is approximately 150 ml, of which 125 ml is intracranial. The ventricles contain about 25 ml, most lying within the lateral ventricles, and the remaining 100 ml is located in the cranial subarachnoid space. CSF is secreted at a rate of 0.35–0.40 ml per minute, which means that normally about 50% of the total volume of CSF is replaced every five to six hours. An effective means of removal from the cranial cavity is thus essential. CSF flows from the lateral ventricles to the third ventricle and then through the cerebral aqueduct to the fourth ventricle. Mixing of CSF from different choroidal sources occurs and is probably assisted by cilia on the ependymal cells lining the ventricles and by arterial pulsations. CSF leaves the fourth ventricle through the medial and lateral apertures to enter the subarachnoid space of the cisterna magna and the subarachnoid cisterns over the front of the pons respectively. The movement of CSF in the subarachnoid space is complex and is characterized by a fast flow component and a much slower bulk flow component. During systole, the major arteries lying in the basal cisterns and other subarachnoid spaces dilate significantly and exert pressure effects on the CSF, causing rapid CSF flow around the brain and out of the cranial cavity into the upper cervical vertebral canal. The pressure wave which causes this outflow of CSF is dispersed through the spinal CSF space, which acts as a capacitance vessel, and is transmitted to the dural venous sinuses through the arachnoid granulations. As the blood within the major arteries passes into the brain in late systole and diastole, CSF re-enters the skull from the spine. This CSF flow occurs at rapid rates and is repeated during every heart cycle. In addition, there is a slow bulk flow of CSF, with a time course measured in hours, which results in circulation of CSF over the cerebral surface in a superolateral direction. CSF is absorbed into the venous system by active diffusion into cerebral capillaries which occurs as a result of the CSF/interstitial pressure differential.

Arachnoid villi and granulations

Arachnoid villi are focal outpushings of the arachnoid mater and subarachnoid space through the wall of dural venous sinuses, very often close to points where veins enter the sinus: granulations have been reported in the superior sagittal, transverse, superior petrosal and straight sinuses in decreasing frequency. They are most prominent along the margins of the great longitudinal fissure, commonly in the lateral lacunae of the superior sagittal sinus, and also protruding directly into the lumen of the sinus (see Ch. 27). They increase in number and size with increasing age and may appear as focal filling defects in the venous sinuses on angiograms and contrast enhanced CT scans and focal signal alterations in the venous sinuses on MR examination.

Arachnoid villi and arachnoid granulations differ in terms of size and complexity. Villi are microscopic structures that are present in the superior sagittal sinus of the fetus and newborn infant. Granulations are visible to the naked eye by the age of 18 months in the parieto-occipital region of the superior sagittal sinus, and by the age of 3 years in the laterally located sinuses of the posterior fossa; they become more lobulated and complex with increasing age, and may become calcified, when they are known as Pacchionian bodies.

At the base of each arachnoid granulation, a thin neck of arachnoid mater projects through an aperture in the dural lining of the venous sinus and expands to form a core
of collagenous trabeculae and interwoven channels (Fig. 16.12). The core is surmounted by an apical cap of arachnoid cells, some 150 µm thick. Channels extend through the cap to reach the subendothelial regions of the granulation. The cap region of each granulation is attached to the endothelium of the sinus over an area some 300 µm in diameter, whereas the rest of the core of the granulation is separated from the endothelium by a fibrous dural cupola.

Fig. 16.12 An arachnoid granulation. 

The function of arachnoid granulations remains controversial. It has long been thought that arachnoid villi and arachnoid granulations constitute the major pathway for the
resorption of CSF from the subarachnoid space into the blood, although the relative contribution each might make to the process is not known and the exact mechanism of resorption has not been determined. Recent studies using radionuclide cisternography and cardiac gated MRI have shown that CSF may also be resorbed throughout the ventricles and subarachnoid space, through the walls of pial and subarachnoid vessels. Moreover, there is a growing body of experimental evidence that significant volumes of CSF may be absorbed into extracranial lymphatics in animals: radiolabelled proteins injected into the CSF (rabbits, cats), brain parenchyma (rabbits) or ventricles (sheep) have been recovered from cervical lymph, possibly by traveling along extensions of the subarachnoid space that surround the olfactory and optic nerves. It has been suggested that extracranial lymphatics play a major role in CSF reabsorption at relatively low pressures, but that other routes, including arachnoid granulations, become increasingly important as CSF pressure rises. A connection between parenchymal interstitial fluid and extracranial lymphatics in humans has yet to be convincingly demonstrated.

An alternative, and not necessarily mutually exclusive, view of arachnoid granulations is that they are involved in dissipating the pressure wave which occurs in the subarachnoid space during arterial systole (caused by the pulsation of the arterial vessels within the space). Since the dural venous sinuses lie within thick non-compliant dural coverings, pressure changes within them functionally represent the extracranial venous compartment: systolic dilatation of the arachnoid granulations would therefore dissipate intracranial pressure changes into the extracranial venous system.

**Hydrocephalus**

Obstruction of the circulation of CSF leads to accumulation of fluid within the ventricular system (hydrocephalus), which causes compression of the brain (Fig. 16.13). Within the brain, critical points at which obstruction may occur correspond to the narrow foramina and passages of the ventricular system. Thus, obstruction of the interventricular foramen causes enlargement of the lateral ventricles; obstruction of the cerebral aqueduct leads to enlargement of both the lateral ventricles and the third ventricle; and obstruction or congenital absence of the apertures of the fourth ventricle leads to enlargement of the entire ventricular system. Hydrocephalus may also occur in the presence of intact communications between the ventricular and subarachnoid spaces (communicating hydrocephalus). The conventional view is that obstructions within the subarachnoid space impair CSF circulation and lead to CSF malabsorption, causing either obstructive or communicating hydrocephalus. Analyses of the intracranial hydrodynamics related to the pulse pressure have suggested that this is an oversimplification, and that increased pulse pressure in the brain capillaries maintains the ventricular enlargement in communicating hydrocephalus and chronic obstructive hydrocephalus (see Greitz 2004 for further details of the haemodynamic theory).
Fig. 16.13. T2-weighted sagittal image of the brain in a patient with obstructive hydrocephalus due to a congenital stenosis of the cerebral aqueduct. The image shows marked dilatation of the third ventricle and proximal aqueduct.
PIA MATER

The pia mater is a delicate membrane which closely invests the surface of the brain, from which it is separated by a microscopic subpial space (Fig. 16.10), and it follows the contours of the brain into concavities and the depths of fissures and sulci. During development, it becomes apposed to the ependyma in the roof of the telencephalon and fourth ventricle to form the stroma of the choroid plexus. The pia mater shares a common embryological origin and structural similarity with the arachnoid mater (see Ch. 27).

Pia mater is formed from a layer of leptomeningeal cells, often only 1 to 2 cells thick, in which the cells are joined by desmosomes and gap junctions but few, if any, tight junctions. The cells are continuous with the coating of the subarachnoid trabeculae and separated from the basal lamina of the glia limitans by bundles of collagen and fibroblast-like cells, and the arteries and veins that lie in the subpial space (Fig. 16.10).

Despite its delicate nature, the pia mater appears to form a regulatory interface between the subarachnoid space and the brain. Pial cells contain enzymes such as catechol-O-methyltransferase and glutamine synthetase (which degrade neurotransmitters), they also exhibit pinocytotic activity and ingest particles up to 1 µm in diameter. Further evidence of the effectiveness of the pia as a barrier is seen in subarachnoid haemorrhage and in subpial haemorrhage in infants, since in neither of these instances do red blood cells penetrate the pia mater.

It was long thought that the subarachnoid space was connected directly with the perivascular spaces (Virchow–Robin spaces) that surround blood vessels in the brain. However, it is now recognized that the pia mater is reflected from the surface of the brain onto the surface of blood vessels in the subarachnoid space, which means that the subarachnoid space is separated by a layer of pia from the subpial and perivascular spaces of the brain.

Zakharov et al., 2004.

The brain is a highly vascular organ, its profuse blood supply characterized by a densely branching arterial network. It has a high metabolic rate that reflects the energy requirements of constant neural activity. It receives about 15% of the cardiac output and utilizes 25% of the total oxygen consumption of the body. The brain is supplied by two internal carotid arteries and two vertebral arteries that form a complex anastomosis (circulus arteriosus, circle of Willis) on the base of the brain. Vessels diverge from this anastomosis to supply the various cerebral regions. In general, the internal carotid arteries and the vessels arising from them supply the forebrain, with the exception of the occipital lobe of the cerebral hemisphere, and the vertebral arteries and their branches supply the occipital lobe, the brain stem and the cerebellum. Venous blood from the brain drains into sinuses within the dura mater (see Ch. 27). Acute interruption of the blood supply to the brain for more than a few minutes causes permanent neurological damage. Such ischaemic strokes along with intracranial haemorrhage are major contemporary sources of morbidity and mortality.

**ARTERIAL SUPPLY OF THE BRAIN**

The arterial supply of the brain is derived from the internal carotid and vertebral arteries, which lie, together with their proximal branches, within the subarachnoid space at the base of the brain.

**INTERNAL CAROTID ARTERY**

The internal carotid arteries (Fig. 17.1) and their major branches (the internal carotid system or ‘anterior’ circulation) supply blood to the majority of the forebrain. Some parts of the occipital and temporal lobes are supplied by branches of the vertebrobasilar system (see Fig. 17.5).
The internal carotid artery arises from the bifurcation of the common carotid artery, ascends in the neck and enters the carotid canal of the temporal bone. Its subsequent course is said to have petrous, cavernous and intracranial parts.

**Petrous part**

The petrous part of the internal carotid artery ascends in the carotid canal, curves anteromedially and then superomedially above the cartilage that fills the foramen lacerum, and enters the cranial cavity. It lies at first anterior to the cochlea and tympanic cavity, and is separated from the latter and the pharyngotympanic tube by a thin, bony lamella that is cribiform in the young and partly absorbed in old age. Further anteriorly, it is separated from the trigeminal ganglion by the thin roof of the carotid canal, although this is often deficient. The artery is surrounded by a venous plexus and by the carotid autonomic plexus, derived from the internal carotid branch.
of the superior cervical ganglion. The petrous part of the artery gives rise to two branches. The caroticotympanic artery is a small, occasionally double, vessel which enters the tympanic cavity by a foramen in the carotid canal and anastomoses with the anterior tympanic branch of the maxillary artery and the stylomastoid artery. The pterygoid artery is inconsistent: when present, it enters the pterygoid canal with the nerve of the same name, and anastomoses with a (recurrent) branch of the greater palatine artery.

Cavernous part

The cavernous part of the internal carotid artery ascends to the posterior clinoid process. It turns anteriorly to the side of the sphenoid within the cavernous sinus and then curves up medial to the anterior clinoid process, to emerge through the dural roof of the sinus. The oculomotor, trochlear, ophthalmic and abducens nerves are lateral to it within the cavernous sinus (see Fig. 27.9). Occasionally, the two clinoid processes form a bony ring round the artery.

This part of the artery gives off a number of small vessels. Cavernous branches supply the trigeminal ganglion, the walls of the cavernous and inferior petrosal sinuses and the nerves contained therein. A minute meningeal branch passes over the lesser wing of the sphenoid to supply the dura mater and bone in the anterior cranial fossa and also anastomoses with a meningeal branch of the posterior ethmoidal artery. Numerous small hypophysial branches supply the neurohypophysis, and are of particular importance because they form the pituitary portal system (Fig. 21.11).

Intracranial part

After piercing the dura mater, the internal carotid artery turns back below the optic nerve to run between it and the oculomotor nerve. It reaches the anterior perforated substance at the medial end of the lateral fissure and terminates by dividing into the anterior and middle cerebral arteries.

Several preterminal vessels leave the cerebral portion of the internal carotid. The ophthalmic artery arises from the anterior part of the internal carotid as it leaves the cavernous sinus, often at the point of piercing the dura, and enters the orbit through the optic canal. The posterior communicating artery (Fig. 17.2, Fig. 17.3) runs back from the internal carotid above the oculomotor nerve, and anastomoses with the posterior cerebral artery (a terminal branch of the basilar artery), thereby contributing to the circulus arteriosus around the interpeduncular fossa. The posterior communicating artery is usually very small. However, sometimes it is so large that the posterior cerebral artery is supplied via the posterior communicating artery rather than from the basilar artery ("fetal posterior communicating artery"); it is often larger on one side only. Small branches from its posterior half pierce the posterior perforated substance together with branches from the posterior cerebral artery. Collectively they supply the medial thalamic surface and the walls of the third ventricle. The anterior choroidal artery leaves the internal carotid near its posterior communicating branch and passes back above the medial part of the uncus. It crosses the optic tract to reach and supply the crus cerebi of the midbrain, then turns laterally, recrosses the optic tract, and gains the lateral side of the lateral geniculate body, which it supplies with several branches. It finally enters the inferior horn of the lateral ventricle via the choroidal fissure and ends in the choroid plexus. This small, but important, vessel also
contributes to the blood supply of the globus pallidus, caudate nucleus, amygdala, hypothalamus, tuber cinereum, red nucleus, substantia nigra, posterior limb of the internal capsule, optic radiation, optic tract, hippocampus and the fimbria of the fornix.

Fig. 17.2 The arteries on the base of the brain. The anterior part of the left temporal lobe has been removed to display the initial course of the middle cerebral artery within the lateral fissure.
Fig. 17.3  The circulus arteriosus on the base of the brain showing the distribution of central (perforating or ganglionic) branches.
ANTERIOR CEREBRAL ARTERY

The anterior cerebral artery is the smaller of the two terminal branches of the internal carotid (Fig. 17.3).

Surgical nomenclature divides the vessel into three parts: A₁ – from the termination of the internal carotid artery to the junction with the anterior communicating artery; A₂ – from the junction with the anterior communicating artery to the origin of the callosomarginal artery; and A₃ – distal to the origin of the callosomarginal artery; this segment is also known as the pericallosal artery.

The anterior cerebral artery starts at the medial end of the stem of the lateral fissure. It passes anteromedially above the optic nerve to the great longitudinal fissure where it connects with its fellow by a short transverse anterior communicating artery. The anterior communicating artery is about 4 mm in length and may be double. It gives off numerous anteromedial central branches that supply the optic chiasma, lamina terminalis, hypothalamus, para-olfactory areas, anterior columns of the fornix and the cingulate gyrus.

The two anterior cerebral arteries travel together in the great longitudinal fissure. They pass around the curve of the genu of the corpus callosum and then along its upper surface to its posterior end, where they anastomose with posterior cerebral arteries (Fig. 17.4). They give off cortical and central branches.

Fig. 17.4 The major arteries supplying the medial, A, and lateral, B, aspects of the brain.

The cortical branches of the anterior cerebral artery are named according to their distribution. Two or three orbital branches ramify on the orbital surface of the frontal lobe and supply the olfactory cortex, gyrus rectus and medial orbital gyrus. Frontal
branches supply the corpus callosum, cingulate gyrus, medial frontal gyrus and paracentral lobule. Parietal branches supply the precuneus, while the frontal and parietal branches both send twigs over the superomedial border of the hemisphere to supply a strip of territory on the superolateral surface (Fig. 17.5). Cortical branches of the anterior cerebral artery therefore supply the areas of the motor and somatosensory cortices that represent the lower limb.

Central branches of the anterior cerebral artery arise from its proximal portion and enter the anterior perforated substance (Fig. 17.3) and lamina terminalis. Collectively, they supply the rostrum of the corpus callosum, the septum pellucidum, the anterior part of the putamen, the head of the caudate nucleus and adjacent parts of the internal capsule. Immediately proximal or distal to its junction with the anterior communicating artery, the anterior cerebral artery gives rise to the medial striate artery which supplies the anterior part of the head of the caudate nucleus and adjacent regions of the putamen and internal capsule.
MIDDLE CEREBRAL ARTERY

The middle cerebral artery is the larger terminal branch of the internal carotid.

Surgical nomenclature divides the vessel into four parts: M₁ – from the termination of the internal carotid artery to the bi/trifurcation, this segment is also known as the sphenoidal; M₂ – the segment running in the lateral (Sylvian) fissure, also known as the insular; M₃ – coming out of the lateral fissure, also known as the opercular; and M₄ – cortical portions.

The middle cerebral artery runs at first in the lateral fissure, then posterosuperiorly on the insula, and divides into branches distributed to the insula and the adjacent lateral cerebral surface (Fig. 17.3, Fig. 17.4, Fig. 17.5). Like the anterior cerebral artery, it has cortical and central branches.

Cortical branches send orbital vessels to the inferior frontal gyrus and the lateral orbital surface of the frontal lobe. Frontal branches supply the precentral, middle and inferior frontal gyri. Two parietal branches are distributed to the postcentral gyrus, the lower part of the superior parietal lobule and the whole inferior parietal lobule. Two or three temporal branches supply the lateral surface of the temporal lobe. Cortical branches of the middle cerebral artery therefore supply the motor and somatosensory cortices that represent the whole of the body (other than the lower limb), the auditory area and the insula.

Small central branches of the middle cerebral artery, the lateral striate or lenticulostriate arteries, arise at its origin and enter the anterior perforated substance together with the medial striate artery. Lateral striate arteries ascend in the external capsule over the lower lateral aspect of the lentiform complex, then turn medially, traverse the lentiform complex and the internal capsule and extend as far as the caudate nucleus.
VERTEBRAL ARTERY

The vertebral arteries and their major branches (sometimes referred to as the 'vertebrobasilar system') essentially supply blood to the upper spinal cord, the brain stem and cerebellum and a significant but variable part of the posterior cerebral hemispheres (Fig. 17.6).

Fig. 17.6 Vertebral arteriograms. A, lateral projection; B, Towne's projection.
The vertebral arteries are derived from the subclavian arteries (see Ch. 30). They ascend through the neck in the foramina transversaria of the upper six cervical vertebrae and enter the cranial cavity through the foramen magnum, close to the anterolateral aspect of the medulla (Fig. 17.2). They converge medially as they ascend the medulla and unite to form the midline basilar artery at approximately the level of the junction between the medulla and pons.

One or two meningeal branches arise from the vertebral artery near the foramen magnum and ramify between the bone and dura mater in the posterior cranial fossa. They supply bone, diploë and the falx cerebelli.

A small anterior spinal artery arises near the end of the vertebral artery, and descends anterior to the medulla oblongata to unite with its fellow from the opposite side at mid-medullary level. The single trunk then descends on the ventral midline of the spinal cord, and is reinforced sequentially by small spinal rami from the vertebral, ascending cervical, posterior intercostal and first lumbar arteries, which all enter the vertebral canal via intervertebral foramina. Branches from the anterior spinal arteries and the beginning of their common trunk are distributed to the medulla oblongata.

The largest branch of the vertebral artery is the posterior inferior cerebellar artery (Fig. 17.6A). It arises near the lower end of the olive and then ascends behind the roots of the glossopharyngeal and vagus nerves to reach the inferior border of the pons. Here it curves and descends along the inferolateral border of the fourth ventricle before it turns laterally into the cerebellar vallecula between the hemispheres, and divides into medial and lateral branches. The medial branch runs back between the cerebellar hemisphere and inferior vermis, and supplies both. The lateral branch supplies the inferior cerebellar surface as far as its lateral border and anastomoses with the anterior inferior and superior cerebellar arteries (from the basilar artery). The trunk of the posterior inferior cerebellar artery supplies the medulla oblongata dorsal to the olivary nucleus and lateral to the hypoglossal nucleus and its emerging nerve roots. It also supplies the choroid plexus of the fourth ventricle and sends a branch lateral to the cerebellar tonsil to supply the dentate nucleus. The posterior inferior cerebellar artery is sometimes absent.

A posterior spinal artery usually arises from the posterior inferior cerebellar artery, but may originate directly from the vertebral artery near the medulla oblongata. It passes posteriorly and descends as two branches which lie anterior and posterior to the dorsal roots of the spinal nerves. These are reinforced by spinal twigs from the vertebral, ascending cervical, posterior intercostal and first lumbar arteries, all of which reach the vertebral canal by the intervertebral foramina, and sustain the posterior spinal arteries to the lower spinal levels.
Minute medullary arteries arise from the vertebral artery and its branches and are distributed widely to the medulla oblongata.
BASILAR ARTERY

The basilar artery is a large median vessel formed by the union of the vertebral arteries at the mid-medullary level (Figs 17.2, 17.3, 17.6). It lies in the pontine cistern, and follows a shallow median groove on the ventral pontine surface, extending to the upper border of the pons. It ends by dividing into two posterior cerebral arteries at a variable level behind the dorsum sellae, usually in the interpeduncular cistern.

Numerous small pontine branches arise from the front and sides of the basilar artery along its course and supply the pons. The long and slender labyrinthine (internal auditory) artery has a variable origin. It usually arises from the anterior inferior cerebellar artery, but variations in its origin include the lower part of the basilar artery, the superior cerebellar artery or, occasionally, the posterior inferior cerebellar artery. The labyrinthine artery accompanies the facial and vestibulocochlear nerves into the internal acoustic meatus and is distributed to the internal ear.

The anterior inferior cerebellar artery (Fig. 17.3) is given off from the lower part of the basilar artery and runs posterolaterally, usually ventral to the abducens, facial and vestibulocochlear nerves. It commonly exhibits a loop into the internal acoustic meatus below the nerves, and when this occurs, the labyrinthine artery may arise from the loop. The anterior inferior cerebellar artery supplies the inferior cerebellar surface anterolaterally and anastomoses with the posterior inferior cerebellar branch of the vertebral artery. A few branches supply the inferolateral parts of the pons and occasionally also supply the upper medulla oblongata.

The superior cerebellar artery (Figs 17.3, 17.6) arises near the distal portion of the basilar artery, immediately before the formation of the posterior cerebral arteries. It passes laterally below the oculomotor nerve, which separates it from the posterior cerebral artery, and curves round the cerebral peduncle below the trochlear nerve to gain the superior cerebellar surface. Here it divides into branches which ramify in the pia mater and supply this aspect of the cerebellum, and also anastomose with branches of the inferior cerebellar arteries. The superior cerebellar artery supplies the pons, pineal body, superior medullary velum and tela choroidea of the third ventricle.
POSTERIOR CEREBRAL ARTERY

The posterior cerebral artery (Figs 17.2, 17.3, 17.4) is a terminal branch of the basilar artery.

Surgical nomenclature divides the vessel into three parts: $P_1$ – from the basilar bifurcation to the junction with the posterior communicating artery; $P_2$ – from the junction with the posterior communicating artery to the portion in the perimesencephalic cistern; and $P_3$ – the portion that runs in the calcarine fissure.

The posterior cerebral artery is larger than the superior cerebellar artery, from which it is separated near its origin by the oculomotor nerve, and, lateral to the midbrain, by the trochlear nerve. It passes laterally, parallel with the superior cerebellar artery, and receives the posterior communicating artery. It then winds round the cerebral peduncle and reaches the tentorial cerebral surface, where it supplies the temporal and occipital lobes. Like the anterior and middle cerebral arteries, the posterior cerebral artery has cortical and central branches.

The cortical branches of the posterior cerebral artery are named according to their distribution. Temporal branches, usually two, are distributed to the uncus, parahippocampal, medial and lateral occipitotemporal gyri. Occipital branches supply the cuneus, lingual gyrus and posterolateral surface of the occipital lobe. Parieto-occipital branches supply the cuneus and precuneus. The posterior cerebral artery supplies the visual areas of the cerebral cortex and other structures in the visual pathway.

The central branches supply subcortical structures. Several small posteromedial central branches arise from the beginning of the posterior cerebral artery (Fig. 17.3) and, together with similar branches from the posterior communicating artery, pierce the posterior perforated substance to supply the anterior thalamus, subthalamus, lateral wall of the third ventricle and globus pallidus. One or more posterior choroidal branches pass over the lateral geniculate body and supply it before entering the posterior part of the inferior horn of the lateral ventricle via the lower part of the choroidal fissure. Branches also curl round the posterior end of the thalamus and pass through the transverse fissure, or go to the choroid plexus of the third ventricle, or traverse the upper choroidal fissure. Collectively these branches supply the choroid plexuses of the third and lateral ventricles and the fornix. Small posterolateral central branches arise from the posterior cerebral artery beyond the cerebral peduncle and supply the peduncle and the posterior thalamus, superior and inferior colliculi, pineal gland and medial geniculate body.
CIRCULUS ARTERIOSUS

The circulus arteriosus (circle of Willis) is a large arterial anastomosis which unites the internal carotid and vertebrobasilar systems (Figs 17.3, 17.6B). It lies in the subarachnoid space within the interpeduncular cistern, and surrounds the optic chiasma and infundibulum. Anteriorly, the anterior cerebral arteries, derived from the internal carotid arteries, are linked by the small anterior communicating artery. Posteriorly, the two posterior cerebral arteries, formed by the division of the basilar artery, are joined to the ipsilateral internal carotid artery by a posterior communicating artery.

There is considerable individual variation in the pattern and calibre of vessels that make up the circulus arteriosus. Although a complete circular channel almost always exists, one vessel is usually sufficiently narrowed to reduce its role as a collateral route and the circle is rarely functionally complete. Cerebral and communicating arteries individually may all be absent, variably hypoplastic, double or even triple. The haemodynamics of the circle are influenced by variations in the calibre of communicating arteries and in the segments of the anterior and posterior cerebral arteries which lie between their origins and their junctions with the corresponding communicating arteries. The greatest variation in calibre between individuals occurs in the posterior communicating artery, which is normally very small, so that only limited flow is possible between the anterior and posterior circulations. Commonly, the diameter of the precommunicating part of the posterior cerebral artery is larger than that of the posterior communicating artery, in which case the blood supply to the occipital lobes is mainly from the vertebrobasilar system. However, sometimes the diameter of the precommunicating part of the posterior cerebral artery is smaller than that of the posterior communicating artery, in which case the blood supply to the occipital lobes is mainly from the internal carotids via the posterior communicating arteries. Since the primary purpose of the vascular circle is to provide anastomotic channels if one vessel is occluded, it is important to note that a normal-sized posterior communicating artery cannot usually fulfil this role. Agenesis or hypoplasia of the initial segment of the anterior cerebral artery are more frequent than anomalies in the anterior communicating artery and contribute to defective circulation in about a third of individuals.

Cerebral aneurysms

Aneurysms are balloon-like swellings which occur on arteries as a result of defects in the vessel wall. They are most commonly found on the vessels of the circulus arteriosus, particularly at or near the junctions of vessels. Aneurysms on the internal carotid artery near its termination may compress the lateral aspect of the optic chiasma, and compromise axons derived from the temporal side of the ipsilateral retina, which causes a defect in the nasal visual field. Aneurysms in the vicinity of the oculomotor nerve, e.g. on the posterior communicating artery, superior cerebellar artery, or the tip of the basilar artery, can cause third nerve palsy by compression (Fig. 17.7).
Fig. 17.7 Intra-arterial digital subtraction angiogram of the right internal carotid artery in a patient with a complete right oculomotor nerve palsy. Lateral projection.

Subarachnoid haemorrhage

Bleeding into the subarachnoid compartment, subarachnoid haemorrhage, is the most common pathology that involves the subarachnoid space. There are many causes; in adults the commonest is rupture of an aneurysm of the intracranial vessels that run within the subarachnoid space. A person who has had a subarachnoid haemorrhage usually complains of a very sudden onset of headache that is frequently described as being their ‘worst ever headache’ or ‘like being hit on the head with a hammer’. When this is suspected the first investigation is an X-ray CT examination which has a very high sensitivity for detecting fresh haemorrhage. Blood will be seen in the basal cisterns and entering the depths of the cortical sulci, i.e. delineating the anatomy of the subarachnoid space, a presentation that permits an accurate diagnosis (Fig. 17.8).
In marked contrast, the spread of blood in a subdural haemorrhage is limited by the arachnoid mater on its deep surface, and the blood therefore remains on the surface of the brain.

Fig. 17.8 Axial CT image (without intravenous contrast agent) at the level of posterior clinoids. There is abnormally high attenuation in the basal cisterns and subarachnoid space of the interhemispheric fissure, indicating an acute subarachnoid haemorrhage, which was subsequently shown to be due to a ruptured aneurysm on the anterior communicating artery.
CENTRAL OR PERFORATING ARTERIES

Numerous small central (perforating or ganglionic) arteries arise from the circulus arteriosus, or from vessels near it (Fig. 17.3). Many of these enter the brain through the anterior and posterior perforated substances. Central branches supply nearby structures on or near the base of the brain together with the interior of the cerebral hemisphere including the internal capsule, basal ganglia and thalamus. These branches form four principal groups. The anteromedial group arises from the anterior cerebral and anterior communicating arteries and passes through the medial part of the anterior perforated substance. These arteries supply the optic chiasma, lamina terminalis, anterior, preoptic and supraoptic areas of the hypothalamus, septum pellucidum, paraolfactory areas, anterior columns of the fornix, cingulate gyrus, rostrum of the corpus callosum and the anterior part of the putamen and the head of the caudate nucleus. The posteromedial group comes from the entire length of the posterior communicating artery and from the proximal portion of the posterior cerebral artery. Anteriorly, these arteries supply the hypothalamus and pituitary gland, and the anterior and medial parts of the thalamus via thalamoperforating arteries. Caudally, branches of the posteromedial group supply the mammillary bodies, subthalamus, the lateral wall of the third ventricle, including the medial thalamus, and the globus pallidus. The anterolateral group is mostly comprised of branches from the proximal part of the middle cerebral artery that are also known as striate, lateral striate or lenticulostriate arteries. They enter the brain through the anterior perforated substance and supply the posterior striatum, lateral globus pallidus and the anterior limb, genu and posterior limb of the internal capsule. The medial striate artery, derived from the middle or anterior cerebral arteries, supplies the rostral part of the caudate nucleus and putamen and the anterior limb and genu of the internal capsule. The posterolateral group is derived from the posterior cerebral artery distal to its junction with the posterior communicating artery, and supplies the cerebral peduncle, colliculi, pineal gland and, via thalamogeniculate branches, the posterior thalamus and medial geniculate body.
REGIONAL ARTERIAL SUPPLY OF THE BRAIN

Brain stem

The medulla oblongata is supplied by the branches of the vertebral, anterior and posterior spinal, posterior inferior cerebellar and basilar arteries, which enter along the anterior median fissure and the posterior median sulcus. Vessels that supply the central substance enter along the rootlets of the glossopharyngeal, vagus, accessory and hypoglossal nerves. There is an additional supply via a pial plexus from the same main arteries.

The pons is supplied by the basilar artery and the anterior inferior and superior cerebellar arteries. Direct branches from the basilar artery enter the pons along the ventral medial groove (basilar sulcus). Other vessels enter along the trigeminal, abducens, facial and vestibulocochlear nerves and from the pial plexus.

The midbrain is supplied by the posterior cerebral, superior cerebellar and basilar arteries. The crura cerebri are supplied by vessels entering on their medial and lateral sides. The medial vessels enter the medial side of the crus and also supply the superomedial part of the tegmentum, including the oculomotor nucleus, and lateral vessels supply the lateral part of the crus and the tegmentum. The colliculi are supplied by three vessels on each side from the posterior cerebral and superior cerebellar arteries. An additional supply to the crura, and the colliculi and their penduncles, comes from the posterolateral group of central branches of the posterior cerebral artery.

Cerebellum

The cerebellum is supplied by the posterior inferior, anterior inferior and superior cerebellar arteries. The cerebellar arteries form superficial anastomoses on the cortical surface. Anastomoses between deeper, subcortical, branches have been postulated.

The choroid plexus of the fourth ventricle is supplied by the posterior inferior cerebellar arteries.

Optic chiasma, tract and radiation

The blood supplies of the optic chiasma, tract and radiation are of considerable clinical importance. The chiasma is supplied in part by the anterior cerebral arteries but its median zone depends upon rami from the internal carotid arteries reaching it via the stalk of the hypophysis. The anterior choroidal and posterior communicating arteries supply the optic tract, and the optic radiation receives blood through deep branches of the middle and posterior cerebral arteries.
**Diencephalon**

The thalamus is supplied chiefly by branches of the posterior communicating, posterior cerebral and basilar arteries. A contribution from the anterior choroidal artery is often noted, but this has been disputed. The medial branch of the posterior choroidal artery supplies the posterior commissure, habenular region, pineal gland and medial parts of the thalamus, including the pulvinar. Small central branches, which arise from the circulus arteriosus and its associated vessels, supply the hypothalamus. The pituitary gland is supplied by hypophysial arteries derived from the internal carotid artery and the anterior cerebral and anterior communicating arteries supply the lamina terminalis.

The choroid plexuses of the third and lateral ventricles are supplied by branches of the internal carotid and posterior cerebral arteries.

**Basal ganglia**

The majority of the arterial supply to the basal ganglia comes from the striate arteries, which are branches from the roots of the anterior and middle cerebral arteries. They enter the brain through the anterior perforated substance and also supply the internal capsule. The caudate nucleus receives blood additionally from the anterior and posterior choroidal arteries. The posteroinferior part of the lentiform complex is supplied by the thalamostriate branches of the posterior cerebral artery. The anterior choroidal artery, a preterminal branch of the internal carotid artery, contributes to the blood supply of both segments of the globus pallidus and the caudate nucleus. Famously, the ligation of this vessel during a neurosurgical procedure on a patient suffering from Parkinson's disease led to alleviation of the Parkinsonian symptoms, presumably as a consequence of infarction of the globus pallidus. This chance observation led to the initiation of pallidal surgery (pallidotomy) for this condition (see also Ch. 22).

**Internal capsule**

The internal capsule is supplied by central, or perforating, arteries which arise from the circulus arteriosus and its associated vessels. These include the lateral and medial striate arteries which come from the middle and anterior cerebral arteries and which also supply the basal ganglia. The lateral striate arteries supply the anterior limb, genu and much of the posterior limb of the internal capsule and are commonly involved in ischaemic and haemorrhagic stroke. One of the larger striate branches of the middle cerebral artery is known as 'Charcot's artery of cerebral haemorrhage'. The medial striate artery, a branch of the proximal part of either the middle or anterior cerebral artery, supplies the anterior limb and genu of the internal capsule and the basal ganglia. The anterior choroidal artery also contributes
to the supply of the ventral part of the posterior limb and the retrolenticular (retrolentiform) part of the internal capsule.

**Ischaemic stroke**

Stroke refers to the clinical syndrome of a rapidly developing focal neurological deficit that is not due to seizure activity. If the cause is lack of, or reduced, blood supply to a portion of the brain then the term ischaemic stroke (see Fig. 17.9) is used, as opposed to haemorrhagic stroke e.g. subarachnoid haemorrhage. The lack of blood flow can be due to pathology in the vessel lumen, such as thrombosis or embolus (common), pathology outside the blood vessel, such as occlusion from mass effect of a tumour or haematoma (rare), or pathology of the vessel wall, such as inflammatory or infective arteritides (rare). The symptoms and signs of ischaemic stroke depend on the location and extent of the arterial infarction. In certain locations, even a small volume stroke can have devastating effects. For example, the internal capsule and most of the adjacent basal ganglia are supplied by small perforating arteries, which are a common site for ischaemic stroke. Corticobulbar and corticospinal motor pathways and third-order thalamocortical sensory fibres all pass through the internal capsule, so that it is effectively the only route connecting the cerebral cortex with other regions of the neuraxis. The neurological deficits that result from stroke in the internal capsule, therefore, may include contralateral spastic hemiparesis, contralateral hemisensory loss and psychological deficits.
It is possible for a major vessel, such as the internal carotid artery in the neck, to become occluded and the individual to remain asymptomatic, if an appropriate flow of blood can be recruited to supply the affected brain region from other sources (collateral supply). The primary role of the circle of Willis
is to allow for this eventuality by redirecting blood from other sources such as the contralateral internal carotid and vertebrobasilar system in the example given above. If the circle of Willis is complete, two or even three of the four major arteries supplying the brain can occlude without producing an ischaemic stroke. Unfortunately the circle of Willis is rarely complete (a finding in approximately 15% of individuals): ischaemic stroke is therefore often caused because the collateral supply is inadequate. For example, an individual in whom neither anterior nor posterior communicating arteries are patent will suffer an ischaemic stroke if there is occlusion of one internal carotid artery, because the proximal anterior and middle cerebral arteries cannot receive collateral flow from the incomplete circle of Willis. Some collateral flow may be available from anastomoses between distal branches of the external carotid artery (e.g. middle meningeal artery), but invariably this is not sufficient to supply the whole hemisphere.

Somewhat paradoxically, the more distal the occlusion occurs in the cerebral vasculature the more likely it is to cause an ischaemic stroke (although the volume of infarcted tissue will be less). This is because the major capacity to form collateralization is proximal, mainly at the circle of Willis. For example, an embolus formed in the proximal internal carotid artery may travel to the M1 portion of the ipsilateral middle cerebral artery and occlude the vessel. There is very little scope for collateralisation at this site and an ischaemic stroke is unavoidable, unless the embolus can be cleared and flow restored in good time.

Cerebral cortex

The entire blood supply of the cerebral cortex comes from cortical branches of the anterior, middle and posterior cerebral arteries (Fig. 17.4, Fig. 17.5). In general, long branches traverse the cortex and penetrate the subjacent white matter for 3 or 4 cm without communicating. Short branches are confined to the cerebral cortex, and form a compact network in the middle zone of the grey matter, whereas the outer and inner zones are sparingly supplied. Although adjacent vessels anastomose on the surface of the brain, they become end arteries as soon as they enter it. In general, superficial anastomoses only occur between microscopic branches of the cerebral arteries, and there is little evidence that they can provide an effective alternative circulation after the occlusion of larger vessels.

The lateral surface of the hemisphere is mainly supplied by the middle cerebral artery. This includes the territories of the motor and somatosensory cortices which represent the whole of the body, apart from the lower limb, and also the auditory cortex and language areas. The anterior cerebral artery supplies a strip next to the superomedial border of the hemisphere, as far back as the parieto-occipital sulcus. The occipital lobe and most of the inferior temporal gyrus (excluding the temporal pole) are supplied by the
posterior cerebral artery.

Medial and inferior surfaces of the hemisphere are supplied by the anterior, middle and posterior cerebral arteries. The area supplied by the anterior cerebral artery is the largest, and extends almost to the parieto-occipital sulcus and includes the medial part of the orbital surface. The rest of the orbital surface and the temporal pole are supplied by the middle cerebral artery, and the remaining medial and inferior surfaces are supplied by the posterior cerebral artery.

Near the occipital pole, the junctional zone between the territories of the middle and posterior cerebral arteries corresponds to the visual (striate) cortex which receives information from the macula. When the posterior cerebral artery is occluded, a phenomenon known as ‘macular sparing’ may occur in which vision with the central part of the retina is preserved. Collateral circulation of blood from branches of the middle cerebral artery into those of the posterior cerebral artery may account for this phenomenon. In addition, in some individuals, the middle cerebral artery may itself supply the macular area.

Watershed areas

Regions of the brain lying at the extreme edges of the major cerebral arterial territories are called watershed areas: they are the first to be deprived of sufficient blood flow in the event of cerebral hypoperfusion. Ischaemic infarcts of the cortex and adjacent subcortical white matter in the border zones between these territories are known as watershed, boundary zone, or border zone infarcts. There is some evidence that a second arterial border zone, the internal arterial border zone, exists within the white matter of the centrum semiovale and corona radiata (between the lenticulostriate perforators and the deep penetrating branches of the distal middle cerebral artery).

Cerebral blood flow

The brain is devoid of either glucose stores or a means of storing oxygen and is, therefore, dependent minute-by-minute upon an adequate blood supply. It has a high metabolic rate in comparison to other organs, which reflects the metabolic demands of constant neural activity. The blood supply of grey matter is more copious than that of white matter.

Cerebral blood flow in the human brain is approximately 50 ml g$^{-1}$ min$^{-1}$. Global cerebral blood flow is autoregulated, i.e. it remains constant in normal individuals despite variations in mean arterial blood pressure over a range of 8.7–18.7 kPa (65–140 mmHg). If the blood pressure falls below this range, cerebral blood flow decreases. Alternatively, if the pressure rises above this
range, cerebral blood flow may increase. Arterial and arteriolar intraluminal pressure directly control contraction of intramural muscle, so that an increase in arterial pressure, for example, causes arterial constriction, and blood flow remains constant.

Although autoregulation normally ensures that global cerebral blood flow remains constant, regional blood flow varies in response to the level of neural activity and, thus, to local metabolic demand. This has been demonstrated for many brain areas including the motor and sensory cortical regions, areas involved in convulsive activity and even cortical areas involved in complex thought processes. The principal local factors affecting regional blood flow are the local hydrogen ion (H\(^+\)) or carbon dioxide concentration, which cause arterial dilatation by both a direct action on the endothelium and through indirect mediators, such as nitric oxide.

Not all substances circulating in arterial blood have access to the brain parenchyma. Particulate matter, such as bacteria, is excluded. In general, lipophilic molecules and small molecules, such as oxygen and carbon dioxide, can cross the blood–brain barrier but hydrophilic ones (excluding glucose) cannot. The cellular basis for the blood–brain barrier is discussed in Chapter 3.
VENOUS DRAINAGE OF THE BRAIN

The venous drainage of the brain occurs through a complex system of deep and superficial veins. These veins possess no valves and have thin walls devoid of muscular tissue. They pierce the arachnoid mater and the inner layer of the dura mater to open into the dural venous sinuses (see Chapter 27).

VENOUS DRAINAGE OF THE POSTERIOR FOSSA

The veins of the brain stem form a superficial venous plexus deep to the arteries.

Veins of the medulla oblongata drain into the veins of the spinal cord or the adjacent dural venous sinuses, or into variable radicular veins which accompany the last four cranial nerves to either the inferior petrosal or occipital sinuses, or to the superior bulb of the jugular vein. Anterior and posterior median medullary veins may run along the anterior median fissure and posterior median sulcus, to become continuous with the spinal veins in corresponding positions. Pontine veins, which may include a median vein and a lateral vein on each side, drain into the basal vein, cerebellar veins, the petrosal sinuses, transverse sinus or the venous plexus of the foramen ovale. Veins of the midbrain join the great cerebral vein or basal vein.

The veins of the cerebellum drain mainly into sinuses adjacent to them or, from the superior surface, into the great cerebral vein. The cerebellar veins course on the cerebellar surface, and consist of superior and inferior groups. Superior cerebellar veins either run anteromedially across the superior vermis to the straight sinus or great cerebral vein, or they run laterally to the transverse and superior petrosal sinuses. Inferior cerebellar veins include a small median vessel that runs backwards on the inferior vermis to enter the straight or sigmoid sinus. Laterally coursing vessels join the inferior petrosal and occipital sinuses.
VENOUS DRAINAGE OF THE CEREBRAL HEMISPHERE

External and internal cerebral veins drain the surfaces and the interior of the cerebral hemisphere (Figs 17.10, 17.11, 17.12, 17.13).

Fig. 17.10 The cerebral venous system showing the principal superficial and deep veins of the brain and their relationship to the dural venous sinuses, viewed from the left side.
Fig. 17.11 The external (superficial) cerebral veins of the left hemisphere and their relationship to the dural venous sinuses.
Fig. 17.12 The internal (deep) cerebral veins, viewed from above after removal of the central portion of the corpus callosum.
External cerebral veins may be divided into three groups, namely superior, middle and inferior.

Eight to 12 superior cerebral veins drain the superolateral and medial surfaces of each hemisphere. They mainly follow the sulci, although some do pass across gyri. They ascend to the superomedial border of the hemisphere, where they receive small veins from the medial surface, and then open into the superior sagittal sinus. Superior cerebral veins in the anterior part of the hemisphere join the sinus almost at right angles. The larger posterior veins are directed obliquely forwards, against the direction of flow in the sinus, an arrangement which may resist their collapse when intracranial pressure is raised.
The superficial middle cerebral vein drains most of the lateral surface of the hemisphere, and follows the lateral fissure to end in the cavernous sinus. A superior anastomotic vein runs posterosuperiorly between the superficial middle cerebral vein and the superior sagittal sinus, thus connecting the superior sagittal and cavernous sinuses. An inferior anastomotic vein courses over the temporal lobe and connects the superficial middle cerebral vein to the transverse sinus. The deep middle cerebral vein drains the insular region and joins the anterior cerebral and striate veins to form a basal vein. Regions drained by the anterior cerebral and striate veins correspond approximately to those supplied by the anterior cerebral artery and the central branches which enter the anterior perforated substance. The basal veins pass back alongside the interpeduncular fossa and midbrain, receive tributaries from this vicinity and join the great cerebral vein.

Inferior cerebral veins on the orbital surface of the frontal lobe join the superior cerebral veins and thus drain to the superior sagittal sinus. Those on the temporal lobe anastomose with basal veins and middle cerebral veins, and drain to the cavernous, superior petrosal and transverse sinuses.

The basal vein begins at the anterior perforated substance by the union of a small anterior cerebral vein, which accompanies the anterior cerebral artery, a deep middle cerebral vein, which receives tributaries from the insula and neighbouring gyri and runs in the lateral cerebral fissure, and striate veins, which emerge from the anterior perforated substance. The basal vein passes back round the cerebral peduncle to the great cerebral vein and receives tributaries from the interpeduncular fossa, inferior horn of the lateral ventricle, parahippocampal gyrus and midbrain.

The internal cerebral vein drains the deep parts of the hemisphere and the choroid plexuses of the third and lateral ventricles. It is formed near the interventricular foramen, behind the column of the fornix, primarily by union of the thalamostriate and choroidal veins, although numerous smaller veins from surrounding structures also converge here. The thalamostriate vein runs anteriorly, between the caudate nucleus and thalamus, and receives many tributaries from both areas. The choroidal vein runs a convoluted course along the whole choroid plexus, and receives veins from the hippocampus, fornix, corpus callosum and adjacent structures. After their formation, the two internal cerebral veins travel back parallel to one another beneath the splenium of the corpus callosum, where they unite to form the great cerebral vein. The great cerebral vein is a short median vessel which curves sharply up around the splenium of the corpus callosum and opens into the anterior end of the straight sinus after receiving the right and left basal veins.

Intracranial venosinus thrombosis

One of the most potentially serious pathologies affecting the intracranial venous system is venosinus thrombosis. In this condition, blood clots within the dural sinuses and/or intracranial veins, and the resulting obstruction of venous drainage, may produce life-threatening complications. In many cases the cause of the venosinus thrombosis is not found: trauma involving the dural sinuses or infections in the vicinity of the sinuses (e.g. mastoiditis) present significant risk. Conditions that increase the coagulability of the blood, such as the oral contraceptive pill, pregnancy, dehydration and inborn abnormalities of the coagulation pathways, are also risk factors.
At its severest, individuals with intracranial venous sinus thrombosis present moribund, in coma or with major seizure activity: in these situations the prognosis is poor. The clot within the dural sinuses and/or cortical veins obstructs the drainage of venous blood from the brain and causes venous hypertension. As the pressure in the venous system approaches the arterial pressure, the blood perfusing the affected parts of the brain decreases. If it decreases below a critical level the brain tissue will become ischaemic and may die (venous infarction). As the arterial supply to the brain is still present, the infarcted areas of the brain frequently undergo major haemorrhage and this is often the factor that kills the patient.

Although they may occur together, clinicians distinguish between thrombosis that affects the ‘superficial’ and ‘deep’ venous systems (Fig. 17.10). Superficial thrombosis usually occurs in the superior sagittal sinus (with or without involvement of the cortical veins), whilst deep intracranial thrombotic disease usually affects the vein of Galen and straight sinus. The parts of the cerebral hemispheres affected are different in the two situations; superficial thrombosis affects the cerebral hemispheres (particularly the white matter) and deep thrombosis affects the thalami and basal ganglia. However, one common feature is the tendency for bilateral involvement, because all of the main draining venous channels are in the midline and accept venous drainage from both hemispheres.

If the extent of the intracranial venosinus thrombosis is less severe, or if alternative venous drainage has been accommodated by reasonable collateral channels, the patient may have more modest symptoms such as headaches or visual disturbance. Those symptoms are due to raised intracranial pressure and if untreated may become chronic.

CHAPTER 18 – Spinal cord: internal organization

The spinal cord provides innervation for the trunk and limbs via spinal nerves and their peripheral ramifications. It receives primary afferent fibres from peripheral receptors located in widespread somatic and visceral structures, and sends motor axons to skeletal muscle. It also contains the cell bodies of all the preganglionic neurones responsible for the sympathetic innervation of cardiac and smooth muscle and secretory glands, and for the parasympathetic innervation of smooth muscle in the distal part of the hind gut, the pelvic viscera and the erectile tissues of the external genitalia. Many bodily functions are regulated at an unconscious level by intraspinal reflex connections between afferent and efferent neurones. Profuse ascending and descending pathways link the spinal cord with the brain, allowing higher centres to monitor and perceive external and internal stimuli and to modulate and control spinal efferent activity.

EXTERNAL FEATURES AND RELATIONS

The topographical anatomy of the spinal cord, its external features and relations are described in more detail in Chapter 43. In brief, the cord lies within the vertebral canal. It is continuous rostrally with the medulla oblongata, just below the level of the foramen magnum (Fig. 28.11) and it terminates caudally as the conus medullaris, which is continuous with the filum terminale and is anchored to the dorsum of the coccyx. The cord is ensheathed by spinal meninges which are continuous with the cranial meninges through the foramen magnum. Although it is approximately circular in cross-section, the diameter of the spinal cord varies according to level; it bears two enlargements, cervical and lumbar.

The spinal cord is essentially a segmental structure, giving rise to 31 bilaterally-paired spinal nerves. These attach to the cord as linear series of smaller dorsal and ventral nerve rootlets. Dorsal rootlets contain afferent nerve fibres and ventral rootlets contain efferent fibres (see Fig. 15.4). Groups of adjacent rootlets coalesce to form dorsal or ventral nerve roots that cross the subarachnoid space and unite to form functionally mixed spinal nerves as they pass through the intervertebral foramina. The dorsal roots bear dorsal root ganglia that contain the cell bodies of primary afferent neurones.
INTERNAL ORGANIZATION

In transverse section, the spinal cord is incompletely divided into symmetrical halves by a dorsal (posterior) median septum and a ventral (anterior) median sulcus (Fig. 18.1). It consists of an outer layer of white matter and an inner core of grey matter; their relative sizes and configuration vary according to level. The amount of grey matter reflects the number of neurones present; it is proportionately largest in the cervical and lumbar enlargements, which contain the neurones that innervate the limbs. The absolute amount of white matter is greatest at cervical levels, and decreases progressively at lower levels, because descending tracts shed fibres as they descend and ascending tracts accumulate fibres as they ascend.

Fig. 18.1 Transverse sections through the spinal cord at representative levels. Approximately ×5. (Figure enhanced by B Crossman.)
A diminutive central canal, lined by columnar, ciliated epithelium (ependyma) and containing cerebrospinal fluid (CSF), extends the whole length of the spinal cord lying in the centre of the spinal grey matter. Rostrally, the central canal extends into the caudal half of the medulla oblongata and then opens into the fourth ventricle.

**SPINAL GREY MATTER**

In three dimensions, the spinal grey matter is shaped like a fluted column (Fig. 43.1F). In transverse section the column is often described as being ‘butterfly-shaped’ or resembling the letter ‘H’ (Fig. 18.1). It consists of four linked cellular masses, the right and left dorsal and ventral horns, that project dorsolaterally and ventrolaterally towards the surface respectively. The grey matter that immediately surrounds the central canal and unites the two sides constitutes the dorsal and ventral grey commissures. The dorsal horn is the site of termination of the primary afferent fibres that enter the cord via the dorsal roots of spinal nerves. The tip of the dorsal horn is separated from the dorsolateral surface of the cord by a thin fasciculus or tract (of Lissauer) in which primary afferent fibres ascend and descend for a short distance before terminating in the subjacent grey matter. The ventral horn contains efferent neurones whose axons leave the spinal cord in ventral nerve roots. A small intermediate, or lateral, horn is present at thoracic and upper lumbar levels; it contains the cell bodies of preganglionic sympathetic neurones.

Spinal grey matter (Fig. 18.2) is a complex mixture of neuronal cell bodies, their processes and synaptic connections, neuroglia and blood vessels. Neurones in the grey matter are multipolar. They vary in size and features such as the length and the arrangement of their axons and dendrites. Neurones may be intrasegmental, i.e. contained within a single segment, or intersegmental, i.e. their ramifications spread through several segments.
Neuronal cell groups of the spinal cord

Viewed from the perspective of its longitudinal columnar organization, the grey matter of the spinal cord consists of a series of discontinuous cell groupings associated with their corresponding segmentally arranged spinal nerves. At any particular cross-sectional level these cell groupings are often considered to correspond approximately with one or more of ten cell layers, known as Rexed's laminae. These laminae are defined on the basis of neuronal size, shape, cytological features and density and are numbered in a dorsoventral sequence.

Laminae I–IV correspond to the dorsal part of the dorsal horn, and are the main site of termination of cutaneous primary afferent terminals and their collaterals. Many
complex polysynaptic reflex paths (ipsilateral, contralateral, intrasegmental and intersegmental) start from this region, as also do many long ascending tract fibres which pass to higher levels. Lamina I (lamina marginalis) is a very thin layer with an ill-defined boundary at the dorsolateral tip of the dorsal horn. It has a reticular appearance, reflecting its content of intermingling bundles of coarse and fine nerve fibres. It contains small, intermediate and large neuronal somata, many of which are fusiform in shape. The much larger lamina II consists of densely packed small neurones, responsible for its dark appearance in Nissl-stained sections. With myelin stains, lamina II is characteristically distinguished from adjacent laminae by the almost total lack of myelinated fibres. Lamina II corresponds to the substantia gelatinosa. Lamina III consists of somata which are mostly larger, more variable and less closely packed than those in lamina II. It also contains many myelinated fibres. Some workers consider that the substantia gelatinosa contains part or all of lamina III as well as lamina II. The ill-defined nucleus proprius of the dorsal horn corresponds to some of the cell constituents of laminae III and IV. Lamina IV is a thick, loosely packed, heterogeneous zone permeated by fibres. Its neuronal somata vary considerably in size and shape, from small and round, through intermediate and triangular, to very large and stellate.

Laminae V and VI lie at the base of the dorsal horn. They receive most of the terminals of proprioceptive primary afferents, profuse corticospinal projections from the motor and sensory cortex and input from subcortical levels, suggesting their involvement in the regulation of movement. Lamina V is a thick layer, divisible into a lateral third and medial two-thirds. Both have a mixed cell population but the former contains many prominent well-staining somata interlaced by numerous bundles of transverse, dorsoventral and longitudinal fibres. Lamina VI is most prominent in the limb enlargements. It has a densely staining medial third of small, densely packed neurones and a lateral two-thirds containing larger, more loosely packed, triangular or stellate somata.

Laminae VII–IX show a variety of forms in the limb enlargements. Lamina VII includes much of the intermediate (lateral) horn. It contains prominent neurones of Clarke’s column (nucleus dorsalis, nucleus thoracis, thoracic nucleus) and intermediomedial and intermediolateral cell groupings (Fig. 18.3). The lateral part of lamina VII has extensive ascending and descending connections with the midbrain and cerebellum (via the spinocerebellar, spinotectal, spinoreticular, tectospinal, reticulospinal and rubrospinal tracts) and is thus involved in the regulation of posture and movement. Its medial part has numerous propriospinal reflex connections with the adjacent grey matter and segments concerned both with movement and autonomic functions. Lamina VIII spans the base of the thoracic ventral horn but is restricted to its medial aspect in limb enlargements. Its neurones display a heterogeneous mixture of sizes and shapes from small to moderately large. Lamina VIII is a mass of propriospinal interneurones. It receives terminals from the adjacent laminae, many commissural fibres from the contralateral lamina VIII, and descending connections from the interstitiospinal, reticulospinal and vestibulospinal tracts and the medial longitudinal fasciculus. The axons from these interneurones influence α motor neurone activity bilaterally, perhaps directly but more probably by excitation of small γ motor neurones supplying efferent fibres to muscle spindles. Lamina IX is a complex array of cells consisting of α and γ motor neurones and many interneurones. The large α motor neurones supply motor end-plates of extrafusal muscle fibres in striated muscle. Recording techniques have demonstrated tonic and phasic α motor neurones. The
former have a lower rate of firing and lower conduction velocity and tend to innervate type S muscle units. The latter have higher conduction velocity and tend to supply fast twitch (type FR, FF) muscle units. The smaller γ motor neurones give rise to small-diameter efferent axons (fusimotor fibres), which innervate the intrafusal muscle fibres in muscle spindles. There are several functionally distinct types of γ motor neurone. The 'static' and 'dynamic' responses of muscle spindles have separate controls mediated by static and dynamic fusimotor fibres, which are distributed variously to nuclear chain and nuclear bag fibres.

---

**Fig. 18.3** The groups of nerve cells in the grey columns of the spinal cord. The relative positions of these columnar groups and their extent through spinal segments are indicated.

Lamina X surrounds the central canal and consists of the dorsal and ventral grey commissures.

Dorsal horn

The dorsal horn is a major zone of termination of primary afferent fibres, which enter the spinal cord through the dorsal roots of spinal nerves. Dorsal root fibres contain numerous molecules, which are either known, or suspected, to fulfil a neurotransmitter or neuromodulator role. These include glutamic acid, substance P, calcitonin gene-related peptide (CGRP), bombesin, vasoactive intestinal polypeptide (VIP), cholecystokinin (CCK), somatostatin, dynorphin and angiotensin II. Dorsal root afferents carry exteroceptive, proprioceptive and interoceptive information. Laminae I–IV are the main cutaneous receptive areas; lamina V receives fine afferents from the skin, muscle and viscera; lamina VI receives proprioceptive and some cutaneous afferents. Most, if not all, primary afferent fibres divide into ascending and descending branches on entering the cord. These then travel for variable distances in the tract of Lissauer, near the surface of the cord, and send collaterals into the subjacent grey matter. The formation, topography and division of dorsal spinal roots have all been confirmed in man.

The lamina marginalis is a thin lamina of neurones at the dorsolateral tip of the dorsal horn, deep to the tract of Lissauer. Beneath it lies the substantia gelatinosa (laminae II and III), which is present at all levels, and consists mostly of small neurones, together with some larger neurones. The substantia gelatinosa receives afferents via the dorsal roots, and its neurones give rise to fibres that form the contralateral spinothalamic tract. The large propriospinal neurones of the nucleus proprius lie ventral to the substantia gelatinosa; they link segments for the mediation of intraspinal coordination (Fig. 18.3).

Clarke’s column lies at the base of the dorsal horn. At most levels, it is near the dorsal white funiculus and may project into it. In the human spinal cord, it can usually be identified from the eighth cervical to the third or fourth lumbar segments. Neurones of Clarke’s column vary in size, but most are large, especially in the lower thoracic and lumbar segments. Some send axons into the dorsal spinocerebellar tracts and others are interneurones.

Lateral horn

The lateral horn is a small lateral projection of grey matter located between the dorsal and ventral horns. It is present from the eighth cervical or first thoracic segment to the second or third lumbar segment. It contains the cell bodies of preganglionic sympathetic neurones. These develop in the embryonic cord dorsolateral to the central canal and migrate laterally, forming intermediomedial and intermediolateral cell columns. Their axons travel via ventral spinal roots and white rami communicantes to the sympathetic trunk. A similar cell group is found in the second to fourth sacral segments, but unlike the thoracolumbar lateral cell column, it does not form a visible lateral projection. It is the source of the sacral outflow of parasympathetic preganglionic nerve fibres.

Ventral horn

Neurones in the ventral horn vary in size. The largest cell bodies, which may exceed
25 µm in diameter, are those of α motor neurones, the axons of which emerge in ventral roots to innervate extrafusal fibres in striated skeletal muscles. Large numbers of smaller neurones, 15–25 µm in diameter, are also present. Some of these are γ motor neurones, which innervate intrafusal fibres of muscle spindles, and the rest are interneurones. Motor neurones utilize acetylcholine as their neurotransmitter.

Considered longitudinally, ventral horn neurones are arranged in elongated groups, and form a number of separate columns, which extend through several segments. These are seen most easily in transverse sections. The ventral horn may be divided into medial, central and lateral cell columns, which all exhibit subdivision at certain levels, usually into dorsal and ventral parts (Fig. 18.3). The medial group extends throughout the cord, but may be absent in the fifth lumbar and first sacral segments. In the thoracic and the upper four lumbar segments, it is subdivided into ventromedial and dorsomedial groups. In segments cranial and caudal to this region, the medial group has only a ventromedial moiety, except in the first cervical segment, where only the dorsomedial group exists.

The central group of cells is the least extensive, and is found only in some cervical and lumbosacral segments. The centrally situated phrenic nucleus, containing the motor neurones that innervate the diaphragm, lies in the third to seventh cervical segments. An irregular accessory group of neurones in the upper five or six cervical segments at the ventral border of the ventral horn give rise to axons that are thought to enter the spinal accessory nerve (Fig. 18.3).

The lateral group of cells in the ventral horn is subdivided into ventral, dorsal and retrodorsal groups, largely confined to the spinal segments which innervate the limbs. The nucleus of Onuf, which is thought to innervate the perineal striated muscles, is a ventrolateral group of cells in the first and second sacral segments.

The motor neurones of the ventral horn are somatotopically organized. The basic arrangement is that medial cell groups innervate the axial musculature, and lateral cell groups innervate the limbs. The basic building block of the somatic motor neuronal populations is represented by a longitudinally disposed group of neurones, which innervate a given muscle, and in which the α and γ motor neurones are intermixed. The various groups innervating different muscles are aggregated into two major longitudinal columns, medial and lateral. In transverse section these form the medial and lateral cell groups in the ventral horn (Fig. 18.4).
The medial longitudinal motor column extends throughout the length of the spinal cord. Its neurones innervate epaxial and hypaxial muscle groups. Basically, epaxial muscles include the erector spinae group (which extend the head and vertebral column), while hypaxial muscles include prevertebral muscles of the neck, intercostal and anterior abdominal wall muscles (which flex the neck and the trunk). The epaxial muscles are innervated by branches of the dorsal primary rami of the spinal nerves, and the hypaxial muscles by branches of the ventral primary rami. In the medial column, motor neurones supplying epaxial muscles are sited ventral to those supplying hypaxial muscles.

The lateral longitudinal motor column is found only in the enlargements of the spinal cord. The motor neurones in this column in the cervical and lumbar enlargements innervate muscles of the upper and lower limbs, respectively. In the cervical enlargement, motor neurones which supply muscles intrinsic to the upper limb are situated dorsally in the ventral grey column, and those innervating the most distal (hand) muscles are sited further dorsally. Motor neurones of the girdle muscles lie in the ventrolateral part of the ventral horn. There is a further somatotopic organization in that the proximal muscles of the limb are supplied from motor cell groups located more rostrally in the enlargement than those supplying the distal muscles. For example, motor neurones innervating intrinsic muscles of the hand are sited in segments C8 and T1, while motor neurones of shoulder muscles are in segments C5 and 6. A similar overall arrangement of motor neurones innervating lower limb muscles applies in the lumbosacral cord (Fig. 18.5).
The main afferent connections to motor neurones are: direct monosynaptic connections from proprioceptive dorsal root afferents in the same or nearby segments; connections from axonal collaterals of dorsal horn and other interneurones; direct monosynaptic connections from the vestibulospinal and corticospinal tracts.

**Spinal reflexes**

The intrinsic connections of the spinal cord and brain stem subserve a number of reflexes by which the functions of peripheral structures are modulated in response to afferent information in a relatively automatic or autonomous fashion. The fundamental components of such reflex 'arcs' are, thus, an afferent and an efferent neurone. However, in all but the simplest of reflexes, interneurones intervene between the
afferent and efferent components, conferring increased versatility and complexity on reflex responses. Reflexes, by their very nature, are relatively fixed and stereotyped in form. Nevertheless, they are strongly influenced and modulated by descending connections. In the case of spinal reflexes these descending controls come from both the brain stem and the cerebral cortex. Pathology of descending supraspinal pathways commonly causes abnormalities of spinal reflex activity, which are routinely tested for in neurological examination. During development, descending control mechanisms suppress what may be regarded as ‘primitive’ spinal reflex responses, such as the extensor plantar reflex and the grasp reflex. When the higher control mechanisms become damaged, these reflexes are released and reappear as a sign of CNS pathology (e.g. the Babinski reflex).

**Stretch reflex**

The stretch reflex is the mechanism by which stretch applied to a muscle elicits its reflex contraction. It is essential for the maintenance of both muscle tone and an upright stance (via the innervation of the postural muscles of the neck, back and lower limbs). Anatomically it is the simplest of reflexes, since it is mediated solely by an afferent and an efferent neurone. The afferent component arises from stretch receptors associated with intrafusal muscle fibres located within muscle spindles. The primary or annulospiral endings of these receptive cells give rise to primary afferent fibres which enter the spinal cord, where they make excitatory synaptic contact directly onto α motor neurones innervating the same muscle (Fig. 18.6). The α motor neurones of antagonistic muscles are simultaneously inhibited via collateral connections to inhibitory interneurones.
As well as α motor neurones innervating extrafusal muscle fibres, muscles also receive γ motor neurones, which innervate intrafusal muscle fibres. Activation of γ motor neurones increases the sensitivity of the intrafusal fibres to stretch (Fig. 18.7). Therefore, changes in γ activity have a profound effect upon the stretch reflex and upon muscle tone. Like α motor neurones, γ motor neurones are under the influence of descending pathways from the brain stem and cerebral cortex. Changes in the activity of the stretch reflex and of muscle tone are commonly found in disorders of the CNS as well as the PNS.

(By permission from Crossman AR, Neary D 2000 Neuroanatomy, 2nd edn. Edinburgh: Churchill Livingstone.)
Painful stimulation of the limbs leads to flexion withdrawal, that is mediated by a polysynaptic reflex (Fig. 18.8) in which interneurones link the afferent and efferent neurones. Thus, activation of nociceptive primary afferents indirectly causes activation of limb flexor motor neurones. Collateralization of fibres to nearby spinal segments mediates flexion of a limb at several joints, depending on the intensity of the stimulus. Decussating connections to the contralateral side of the cord activate α motor neurones innervating corresponding extensor muscles, which produces the so-called crossed extensor reflex. In principle, virtually any cutaneous stimulus has the potential to induce a flexor reflex, but, other than in the case of noxious stimuli, this response is normally inhibited by descending pathways. When descending influences are lost, even harmless cutaneous stimulation can elicit flexion of the limbs. The Babinski (extensor plantar) reflex, which is generally regarded as pathognomonic of damage to the corticospinal tract, is part of a flexion withdrawal of the lower limb in response to stimulation of the sole of the foot.
Fig. 18.8 The flexor reflex and crossed extensor reflex.
(By permission from Crossman AR, Neary D 2000 Neuroanatomy, 2nd edn. Edinburgh: Churchill Livingstone.)
SPINAL WHITE MATTER

The spinal white matter surrounds the central core of grey matter. The white matter consists primarily of longitudinally running nerve fibres. Fibres subserving related functions, or those with common origins or destinations, are generally grouped together anatomically to form tracts (fasciculi), which may be ascending, descending and propriospinal. Ascending tracts consist either of primary afferent fibres, that enter the cord via the dorsal roots of spinal nerves, or fibres derived from intrinsic spinal neurones, that carry afferent impulses to supraspinal levels. Descending tracts contain fibres that descend from the cerebral cortex or brain stem nuclei to control the activity of spinal neurones. Propriospinal tracts contain the axons of neurones that are localized entirely to the spinal cord: they contain both ascending and descending components, collectively mediating intersegmental coordination.

The spinal white matter is conventionally described as being arranged into three large, bilaterally paired masses, the dorsal, lateral and ventral funiculi, each of which contains a number of predominantly specific tracts (see Fig. 18.1 and Fig. 18.9). Narrow dorsal and ventral white commissures run between the two halves of the cord.
Fibres in the spinal white matter vary in calibre. Many are small and lightly, or non-, myelinated. Most regions contain a wide spectrum of fibre diameters, from 1 µm or less to 10 µm. Some tracts typically contain only small fibres, e.g. the dorsolateral tract, fasciculus gracilis and central part of the lateral funiculus. The fasciculus cuneatus, anterior funiculus and peripheral zone of the lateral funiculus all contain many large-diameter fibres.

Whilst the ascending and descending tracts are to a large extent discrete and regularly located, significant overlap between adjacent tracts does occur. Their general disposition is shown in Fig. 18.9.

**Ascending pathways**

**Dorsal columns**

The dorsal funiculus consists of two large ascending tracts, the fasciculus gracilis and fasciculus cuneatus (Fig. 18.10), that are also known as the dorsal columns. They are separated by a posterointermediate septum. The dorsal columns contain a high proportion of myelinated fibres carrying proprioceptive (position sense and kinaesthesia), exteroceptive (touch-pressure) and vibratory sensation to higher levels. These fibres come from several sources: long primary afferent fibres which enter the cord in the dorsal roots of spinal nerves and ascend to the dorsal column nuclei in the medulla oblongata; shorter primary afferent fibres projecting to neurones of Clarke’s column and other spinal neurones; axons from secondary neurones of the spinal cord.
ascending to the dorsal column nuclei. The dorsal columns also contain axons of propriospinal neurones.

Fig. 18.10 The dorsal columns. Primary afferent fibres from different levels and their associated second- and third-order neurones are depicted in different colours.

The fasciculus gracilis begins at the caudal end of the spinal cord. It contains long ascending branches of primary afferents, which enter the cord through ipsilateral dorsal spinal roots and ascending axons of secondary neurones in laminae IV to VI of the ipsilateral dorsal horn. As the fibres ascend, they are joined by axons of successive dorsal roots. Fibres entering in coccygeal and lower sacral regions are shifted medially by successive additions of fibres entering at higher levels.

The fasciculus gracilis lies medial to the fasciculus cuneatus in the upper spinal cord (Fig. 18.9). At upper cervical levels the fasciculus gracilis contains a larger proportion
of afferents from cutaneous receptors than from deep proprioceptors because many of
the latter leave the fasciculus at lower segments to synapse in Clarke's column.
Indeed, proprioception from the lower limb mostly reaches the thalamus by relaying in
Clarke's column and then again in nucleus Z (p. 280). Axons of the fasciculus gracilis,
from both primary and secondary neurones, terminate in the nucleus gracilis of the
dorsal medulla.

The fasciculus cuneatus (Fig. 18.9) begins at midthoracic level and lies lateral to the
fasciculus gracilis. It is composed mostly of primary afferent fibres of the upper
thoracic and cervical dorsal roots. At upper cervical levels it contains a large
population of afferents from both deep and cutaneous receptors of the upper limb. In
addition, some of its axons arise from secondary neurones in laminae IV–VI of the
ipsilateral dorsal horn. Many axons (both primary and secondary) that ascend in the
fasciculus cuneatus terminate in the nucleus cuneatus of the dorsal medulla. Some
also end in the lateral (external or accessory) cuneate nucleus; neurones in this
nucleus project to the cerebellum via the cuneocerebellar pathway.

Many ascending fibres of the fasciculus gracilis and fasciculus cuneatus terminate by
synapsing on neurones of the dorsal column nuclei (nucleus gracilis and nucleus
cuneatus, respectively) in the medulla oblongata. (The connections of the dorsal
column nuclei are described further with the medulla oblongata, p. 280.) Axons arising
from neurones in the dorsal column nuclei arch ventromedially round the central grey
matter of the medulla as internal arcuate fibres (Fig. 19.5) and decussate in the great
sensory decussation (decussation of the medial lemniscus) to form the medial
lemniscus itself. They ascend to the ventral posterolateral nucleus of the thalamus,
from where neurones project to the somatosensory cortex in the postcentral gyrus of
the parietal lobe (areas 3, 1 and 2). Some neurones of the dorsal column nuclei form
posterior external arcuate fibres which enter the cerebellum.

The high degree of somatotopic organization that is present in the dorsal columns is
preserved as the pathways ascend through the dorsal column nuclei and thalamus to
reach the primary somatosensory cortex. In the dorsal column nuclei, the lower limb is
represented in the nucleus gracilis, the upper limb in the nucleus cuneatus, and the
trunk is represented in an intermediate position between them. Fibres are also
segregated by modality in the dorsal columns: fibres from hair receptors are most
superficial, while those from tactile and vibratory receptors lie in deeper layers.

Spinocerebellar tracts

There are two principal spinocerebellar tracts: dorsal (posterior) and ventral (anterior).
They occupy the periphery of the lateral aspect of the spinal white matter (Fig. 18.9,
Fig. 18.11) and carry proprioceptive and cutaneous information to the cerebellum for
the coordination of movement. Both tracts contain large-diameter myelinated fibres,
but there are more in the dorsal tract. Finer-calibre fibres are associated with the
ventral tract.
The dorsal spinocerebellar tract lies lateral to the lateral corticospinal tract. It begins about the level of the second or third lumbar segment and enlarges as it ascends. Axons of the tract originate ipsilaterally from the larger neurones of Clarke's column, in lamina VII throughout spinal segments T1–L2. Clarke's column receives input from collaterals of long ascending primary afferents of the dorsal columns and terminals of shorter ascending primary afferents of the dorsal columns. Many of these afferent fibres ascend from segments caudal to L2. In the medulla, the dorsal spinocerebellar tract passes through the inferior cerebellar peduncle to terminate ipsilaterally in the rostral and caudal parts of the cerebellar vermis.
The ventral spinocerebellar tract lies immediately ventral to the dorsal tract. The cells of origin are in laminae V–VII of the lumbosacral cord and the tract carries information from the lower limb. Most of the axons forming the tract decussate, but some remain ipsilateral. The tract begins in the upper lumbar region and ascends through the medulla oblongata to reach the upper pontine level, from where it descends in the dorsal part of the superior cerebellar peduncle to terminate, mainly contralaterally, in the anterior cerebellar vermis.

The spinocerebellar tracts are organized such that fibres from lower spinal segments are most superficial. Both tracts convey proprioceptive and exteroceptive information, but they are functionally different. Neurones of Clarke’s column are excited monosynaptically by la and Ib primary afferent fibres (from muscle spindles and tendon organs, respectively) and also by group II muscle afferents, and cutaneous touch and pressure afferents. The proprioceptive impulses often arise from a single muscle or from synergistic muscles acting at a common joint. Thus, the dorsal spinocerebellar tract transmits modality-specific and space-specific information that is used in the fine coordination of individual limb muscles. On the other hand, the cells of the ventral tract are activated monosynaptically by Ib afferents and transmit information from large receptive fields that include different segments of a limb. The ventral tract lacks subdivisions for different modalities and transmits information for the coordinated movement and posture of the entire lower limb.

Since Clarke’s column diminishes rostrally (Fig. 18.3) and does not extend above the lowest cervical segment, it follows that the dorsal spinocerebellar tract carries information from the trunk and lower limb. Proprioceptive and exteroceptive information from the upper limb travel in primary afferent fibres of the fasciculus cuneatus. These fibres end somatotopically in the accessory (external or lateral) cuneate nucleus and the adjoining part of the cuneate nucleus situated in the medulla oblongata. Cells of these nuclei give rise to the posterior external arcuate fibres that form the cuneocerebellar tract (Fig. 18.11), which enters the cerebellum via the ipsilateral inferior cerebellar peduncle. The accessory cuneate nucleus and the lateral part of the cuneate nucleus are considered to be homologous to the cells of Clarke’s column. The cuneocerebellar tract is, therefore, functionally allied to the dorsal spinocerebellar tract, and is its upper limb equivalent.

Axons of all the spinocerebellar tracts and the cuneocerebellar tract form part of the ‘mossy-fibre system’. They end in the cerebellar cortex in a highly organized, somatotopical and functional pattern (p. 302).

**Spinothalamic tracts**

The spinothalamic tracts (Fig. 18.9) consist of second-order neurones which convey pain, temperature, coarse (non-discriminative) touch and pressure information to the somatosensory region of the thalamus. The cells of origin lie in various laminae of all segments of the spinal cord. Fibres decussate in the ventral white commissure to reach the contralateral spinothalamic tracts: pain and temperature fibres do so promptly, within about one segment of their origin, whilst fibres carrying other modalities may ascend for several segments before crossing. Spinothalamic fibres mostly ascend in the white matter ventrolateral to the ventral horn, partly intermingled with ascending spinoreticular fibres and descending reticulospinal fibres. Some authorities describe two spinothalamic tracts (lateral and ventral) with more-or-less
distinct anatomical locations and functions. However, physiological studies in animals support the notion that these tracts may be best considered as a structural and functional continuum.

The lateral spinothalamic tract (Fig. 18.12) is sited in the lateral funiculus, lying medial to the ventral spino cerebellar tract. Clinical evidence indicates that it subserves pain and temperature sensations. The ventral spinothalamic tract (Fig. 18.13) lies in the anterior funiculus medial to the point of exit of the ventral spinal nerve roots and dorsal to the vestibulospinal tract, which it overlaps. On the basis of clinical evidence, it subserves coarse tactile and pressure modalities.

![Fig. 18.12 The lateral spinothalamic tract.](Redrawn from Carpenter MB 1991 Core Text of Neuroanatomy, 4th edn. Baltimore: Williams and Wilkins, by permission of author and publisher.)
A dorsolateral spinothalamic tract has been described in animals. The axons arise mainly from neurones in lamina I, and cross to ascend in the contralateral dorsolateral funiculus. These neurones respond maximally to noxious, mechanical and thermal cutaneous stimuli. Examples of clinical pain relief following dorsolateral cordotomy suggest that a similar projection exists in man.

On reaching the lower brain stem, spinothalamic tract axons separate. Axons in the ventral tract join the medial lemniscus. Axons in the lateral tract continue as the spinal lemniscus.
There is clear somatotopic organization of the fibres in the spinothalamic tracts throughout their extent. Fibres crossing at any cord level join the deep aspect of those that have already crossed, which means that both tracts are segmentally laminated (Fig. 18.14). Somatotopy is maintained throughout the medulla oblongata and pons. In the midbrain, fibres in the spinal lemniscus conveying pain and temperature sensation from the lower limb extend dorsally, while those from the trunk and upper limb are more ventrally placed. Both lemnisci ascend to end in the thalamus. The major spinothalamic projections in man are to the ventral posterolateral nucleus, and also to the centrolateral intralaminar nucleus.

Fig. 18.14 General plan of the segmental organization of fibres in the dorsal funiculus, the lateral corticospinal tract and the spinothalamic tracts. The probable cross-sectional areas of these tracts are schematically enlarged. This general plan applies to all segmentally organized tracts whether ascending, descending, ipsilateral or contralateral.

Neurones of the spinothalamic tracts
The specific localization of spinothalamic tract cell bodies is poorly documented in man. In animals, about a third are localized to the upper three cervical segments. About 20% are located in lower cervical segments, 20% in the thoracic region (mostly in segments T1–3), 20% in the lumbar region and 10% in the sacrococcygeal cord. Cells are located in laminae I and IV–VIII, the greatest concentration being in laminae VI and VII. Cell bodies giving rise to spinothalamic tract axons are predominantly contralateral, although a relatively small number (10%), mostly in the upper three cervical segments, are ipsilateral.

Neurones of the spinothalamic tracts have very different receptive fields. Specificity of separate channels, as it exists in the dorsal column nuclei, is absent in the laminae of the cord. Convergence of different functional types of afferent fibres onto an individual tract cell is a common feature in the cord. On the basis of laminar site, functional properties, and specific thalamic termination of their axons, spinothalamic tract neurones may be divided into three separate groups. These are the apical cells of the dorsal grey column (lamina I), deep dorsal column cells (laminae IV–VI), and cells in the ventral grey column (laminae VII, VIII). There are species differences and the description below is derived from studies in non-human primates.

Lamina I cells which project to the thalamus show the following characteristics. In essence they respond maximally to noxious or thermal cutaneous stimulation, and consist mainly of high-threshold, but also some wide-dynamic-range, units. Their receptive fields are usually small, representing a part of a digit or a small area of skin involving several digits. Lamina I spinothalamic tract neurones receive input from Aδ and C fibres, and some respond to convergent input from deep somatic and visceral receptors. Spinothalamic tract cells in the thoracic cord display marked viscerosomatic convergence. Lamina I spinothalamic tract neurones project preferentially to the ventral posterolateral nucleus of the thalamus, with limited projections to the centrolateral and mediodorsal thalamic nuclei. The population of deep dorsal column (laminae IV–VI) spinothalamic neurones of the lumbar cord contains wide-dynamic-range (60%), high-threshold (30%), and low-threshold (10%) type units. They can code accurately both innocuous and noxious cutaneous stimuli. Some cells also respond to input from deep somatic and visceral receptors. In the lumbar cord their receptive fields are small or medium sized; they are larger than the area of the foot, but smaller than the entire leg. In the thoracic cord the fields of these laminar cells are larger, and often include the entire upper limb plus part of the chest. Many of the deep dorsal grey column spinothalamic tract neurones in the thoracic segments receive convergent input from sympathetic afferent fibres. Laminae IV–VI spinothalamic tract units project either to the ventral posterolateral nucleus or to the centrolateral nucleus of the thalamus, and sometimes to both. Units projecting to the ventral posterolateral nucleus receive input from all classes (Aβ, Aδ and C) of cutaneous fibres.

Ventral grey column (laminae VII and VIII) spinothalamic tract cells respond mainly to deep somatic (muscle and joint) stimuli, but also to innocuous and/or noxious cutaneous stimuli. In the thoracic regions of the spinal cord they also receive convergent input from visceral sources. The majority of laminae VII and VIII spinothalamic tract neurones have large, complex receptive fields (often bilateral), which encompass widespread areas of the body. Cells of this group, which project exclusively to the medial thalamus, receive input from Aβ, Aδ and C classes of afferent fibres, and many respond to convergent input from receptors of deep structures. This population of neurones contains wide-dynamic-range (25%), high-
threshold (63%), and low-threshold (12%) units. Most of the spinothalamic tract cells in the ventral grey column project to the intralaminar nuclei of the thalamus. Wide-dynamic-range type neurones are particularly effective for discriminating between different intensities of painful stimulation.

**Pain mechanisms**

The ascending connections through which sensory information reaches higher centres are not simple relays, since it is known that they are subject to modulation by intraspinal connections and by descending pathways from the brain stem and cerebral cortex. This is particularly important in relation to the spinothalamic and spinoreticular pathways and the perception of pain.

Presynaptic inhibition influences many, possibly all, primary afferent terminals. A much-investigated site of presynaptic effects is the substantia gelatinosa. It has been proposed that impulses from cutaneous (and other) afferents are here subject to tonic control by presynaptic modulation of primary afferent terminals, mediated by small neurones of the substantia gelatinosa.

The ‘gate control theory’ (Melzack & Wall 1965) proposed a mechanism for the modulation of inflow of information along nociceptive and other afferent pathways (Fig. 18.15). The hypothesis was that large-diameter afferents (e.g. from hairs and touch corpuscles) are excitatory to the large neurones of lamina IV, from which spinothalamic fibres arise, and to interneurones in the substantia gelatinosa. In contrast, fine non-myelinated afferents are excitatory to tract cells but inhibitory to the interneurones. The axons of substantia gelatinosa interneurones are presumed to inhibit presynaptically the terminals of all afferents that synapse with tract cells. In such a system, low activity in the fine afferents inhibits the interneurones, and so prevents them inhibiting tract cells. Hence the ‘gate’ to cells in lamina IV is opened to transmit intermittent, small volleys of impulses from the large fibres. A prolonged high-frequency volley of impulses in the large-diameter afferents would be transmitted to lamina IV tract cells initially, but this would soon cease as activity in the interneurones closed the gate. Conversely, a persistent high activity in the fine afferents would open the gate resulting in massive bombardment of neurones of lamina IV (which include some neurones of high threshold that are only activated by such bombardment). It was assumed that onward transmission in the lateral spinothalamic tract would evoke the perception of pain at supraspinal levels. Pain, therefore, would result from an imbalance between the varieties of afferent impulses when there was a disproportionately large traffic along the fine afferents. In fact, inhibition of spinothalamic tract neurones can be produced by electrical stimulation of peripheral nerves, the most effective being volleys which activate Aδ fibres.
The basic arrangement of the sensory 'gate' mechanism in the dorsal laminae of the grey matter of the spinal cord.

The activity of spinothalamic tract neurones may also be selectively modulated by pathways descending from the brain to the spinal cord. Many studies have shown that the response of spinothalamic tract cells to noxious stimuli is inhibited by stimulation of certain brain regions. This is obviously of considerable clinical interest in the treatment of chronic, intractable, pain.

In the brain stem, the regions inducing such effects correspond to a number of midbrain and rhombencephalic nuclei which, with their connections, constitute an endogenous analgesic system. In the midbrain, these regions are the periaqueductal grey matter, dorsal raphe nucleus and part of the cuneiform nucleus. Neurones in these sites contain serotonin (5-HT), γ-aminobutyric acid (GABA), substance P, CCK, neurotensin, enkephalin and dynorphin. The periaqueductal grey matter receives afferents from the frontal somatosensory and cingulate neocortex, the amygdala, numerous local reticular nuclei and the hypothalamus. Afferents from the latter are separate bundles, which carry histamine, luteinizing hormone-releasing hormone (LHRH), vasopressin, oxytocin, adrenocorticotropic hormone (ACTH), melanocyte-stimulating hormone (γ-MSH), endorphin, and angiotensin II. Some fibres descend from the periaqueductal grey matter to rhombencephalic centres, others pass directly to the spinal cord.

In the rhombencephalon, the nucleus raphe magnus and the medial reticular column constitute an important multineuromediator centre. Neurones in these sites contain serotonin, substance P, CCK, thyrotrophin-releasing hormone (TRH), enkephalin and dynorphin: some neurones contain two or even three neuromediators. Descending bulbospinal fibres pass to the nucleus of the spinal tract of the trigeminal nerve and its continuation, the substantia gelatinoasa. The latter extends throughout the length of the cord and contains populations of neurones that express many different neuromediators, e.g. GABA, substance P, neurotensin, enkephalin and dynorphin. There is abundant physiological and pharmacological evidence that all of these regions are intimately concerned with the control of nociceptive (and probably other modality) inputs.
Stimulation of forebrain sites including the periventricular grey matter, the ventral posteroateral nucleus of the thalamus, and the primary sensory (SI) and posterior parietal cortices, inhibit spinothalamic tract cells. In contrast, some spinothalamic tract cells are excited by stimulation of the medullary reticular formation, and the primary motor cortex (the latter effect probably being mediated by the corticospinal tract).

The perception of pain is further described in Chapter 23.

**Spinoreticular pathway**

Spinoreticular fibres are intermingled with those of the spinothalamic tracts, and ascend in the ventrolateral quadrant of the spinal cord (Fig. 18.16). Evidence from animal studies suggests that cells of origin occur at all levels of the spinal cord, particularly in the upper cervical segments. Most neurones are in lamina VII, some are in lamina VIII, and others are in the dorsal horn, especially lamina V. Most axons in the lumbar and cervical enlargements cross the midline, but there is a large uncrossed component in cervical regions. Most axons are myelinated. The pattern of anterograde degeneration, in both human postmortem studies and in experimental animals following anterolateral cordotomy, indicates the existence of spinoreticular projections to many nuclei of the medial pontomedullary reticular formation. There is also a projection to the lateral reticular nucleus (a precerebellar relay nucleus). These projections do not appear to be somatotopically organized. Spinoreticular neurones respond to inputs from the skin or deep tissues. Innocuous cutaneous stimuli may inhibit or excite a particular cell, whereas noxious stimuli are often excitatory. A spinoreticulo-thalamo-cortical pathway has been proposed as an important route serving pain perception. Like other ascending pathways, the tract cells are influenced by descending control. For example, electrical stimulation of the periaqueductal grey matter inhibits the responses of certain spinoreticular cells to input from cardiopulmonary afferents. Stimulation of the reticular formation also alters the activity of spinoreticular neurones.
Spinocervicothalamic pathway

The lateral cervical nucleus is small in man. It lies in the lateral funiculus, ventrolateral to the dorsal horn in the upper two cervical segments. In some human cord specimens the nucleus is not distinctly defined, and is possibly incorporated into the dorsal horn. It receives axons from the spinocervical tract, which ascends in the dorsolateral funiculus. The tract cells are found in laminae III–V at all levels of the spinal cord, ipsilateral to the nucleus. Most neurones of the nucleus project to the contralateral thalamus via the medial lemniscus, and some project to the contralateral midbrain. Specific thalamic targets include the ventral posterolateral nucleus and part of the
posterior complex. Spinocervical tract neurones respond to hair movement, pressure, pinch and thermal stimuli and to high-threshold muscle input; many also respond to noxious stimuli. Like tract cells of other ascending pathways, they are under tonic descending inhibitory control.

**Spinomesencephalic pathway**

The spinomesencephalic pathway consists of a number of tracts ascending from the spinal cord to various regions of the midbrain. It includes the spinotectal tract projecting to the superior colliculus, neurones synapsing in the periaqueductal grey matter, and other spinal cord projections which terminate in the parabrachial nucleus, the pretectal nuclei and the nucleus of Darkschewitsch. Cells of origin are located throughout the length of the spinal cord, particularly in the cervical segments and the lumbosacral enlargement, mostly in lamina I, but they are also present in laminae IV–VIII, where they are concentrated in lamina V. Most are contralateral, but a prominent ipsilateral group is also found at upper cervical levels. Spinomesencephalic fibres are mostly myelinated and ascend in the white matter of the ventrolateral quadrant of the spinal cord, in association with the spinothalamic and spinoreticular tracts.

Spinomesencephalic neurones are of low-threshold, wide-dynamic-range, or high-threshold classes. Their receptive fields may be small, or very complex and encompass large surface areas of the body. Many spinomesencephalic cells are nociceptive and are likely to be involved in the motivational–affective component of pain. Electrical stimulation of their site of termination in the periaqueductal grey matter results in severe pain in man. Furthermore, the cells of the deeper layers of the superior colliculus, where spinotectal fibres synapse, are activated by noxious stimuli.

**Spino-olivary tract**

The spino-olivary tract is described in animals as arising from neurones in the deeper laminae of grey matter. Axons forming the tract cross and then ascend superficially at the junction of the anterior and lateral white funiculi, to end in the dorsal and medial accessory olivary nuclei. The tract carries information from muscle and tendon proprioceptors, and also from cutaneous receptors. A functionally similar route, the dorsal spino-olivary tract, ascends in the dorsal white funiculi, and relays in the dorsal column nuclei to the contralateral inferior olivary nucleus. Information on these tracts in primates is scant, but postmortem evidence following cordotomies in man has revealed degenerating axonal terminals in the inferior olivary nucleus.

**Descending tracts**

Descending pathways to the spinal cord originate primarily from the cerebral cortex and from numerous sites within the brain stem (Fig. 18.16, Fig. 18.17, Fig. 18.18). They are concerned with the control of movement, muscle tone and posture, the modulation of spinal reflex mechanisms and the transmission of afferent information to higher levels. They also mediate control over spinal autonomic neurones.
Fig. 18.17 The corticospinal tracts.
(Redrawn from Carpenter MB 1991 Core Text of Neuroanatomy, 4th edn. Baltimore: Williams and Wilkins, by permission of author and publisher.)
Corticospinal and corticobulbar tracts

Corticospinal and corticobulbar fibres arise from neurones in the cerebral cortex. They project, in a somatotopically organized fashion, to neurones that are mostly located in the contralateral side of the spinal cord or brain stem respectively (Fig. 18.17). The majority of corticospinal and corticobulbar fibres arise from cells situated in the primary motor cortex (area 4) and the premotor cortex (area 6). A small contribution comes from cells in the postcentral gyrus (somatosensory cortex; areas 3, 1, and 2) and the adjacent parietal cortex (area 5). In the monkey, 30% of corticospinal fibres arise from area 4, 30% from area 6, and 40% from the parietal regions. Cells of origin of corticospinal and corticobulbar fibres vary in size in the different cortical areas and
are clustered into groups or strips. The largest cells (giant pyramidal neurones, or Betz cells) are located in the primary motor cortex of the precentral gyrus.

Corticospinal and corticobulbar fibres descend through the subcortical white matter to enter the genu and posterior limb of the internal capsule. They then pass through the ventral part of the midbrain in the crus cerebri. As they continue caudally through the pons they are separated from its ventral surface, and fragmented into fascicles, by transversely running pontocerebellar fibres. Corticobulbar fibres leave to terminate in association with the cranial nerve motor nuclei of the midbrain, pons and medulla. In the medulla oblongata, the residual corticospinal fibres form a discrete bundle, the pyramid (Fig. 19.2) which forms a prominent longitudinal column on the ventral surface of the medulla. The corticospinal tract is, therefore, also referred to as the pyramidal tract. Each pyramid contains about a million axons of varying diameter. The majority (70%) are myelinated: most (90%) have a diameter of 1–4 µm; 9% have diameters of 5–10 µm; and less than 2% have diameters of 11–22 µm. The largest diameter axons arise from the giant Betz cells.

Just rostral to the level of the spinomedullary junction, approximately 75–90% of the corticospinal fibres in the pyramid cross the median plane in the pyramidal decussation (decussation of the pyramids) and continue caudally as the lateral corticospinal tract. The rest of the fibres continue uncrossed as the ventral corticospinal tract. The lateral tract also contains some uncrossed corticospinal fibres. The lateral corticospinal tract (Fig. 18.17) descends in the lateral funiculus throughout most of the length of the spinal cord. It occupies an oval area, ventrolateral to the dorsal horn and medial to the dorsal spinocerebellar tract (Fig. 18.9). In the lumbar and sacral regions, where the dorsal spinocerebellar tract is absent, the lateral corticospinal tract reaches the dorsolateral surface of the cord. As it descends, the tract diminishes in size as its fibres terminate in progressively lower spinal segments until about the fourth sacral segment: its axons terminate on ipsilateral spinal neurones.

The smaller ventral corticospinal tract (Fig. 18.17) descends in the ventral funiculus. It lies close to the ventral median fissure, and is separated from it by the sulcomarginal fasciculus (Fig. 18.9). The ventral corticospinal tract diminishes as it descends and usually disappears completely at midthoracic cord levels. It may either be absent or, very rarely, contain almost all the corticospinal fibres. Near their termination, most fibres of the tract cross the median plane in the ventral white commissure to synapse on contralateral neurones. The vast majority of corticospinal fibres, irrespective of the tract in which they descend, therefore terminate in the spinal cord on the side contralateral to their cortical origin.

Knowledge of the detailed termination of corticospinal fibres is based largely upon animal studies, but is supplemented by data from postmortem studies on human brains using anterograde degeneration methods. Most corticospinal fibres are believed to terminate contralaterally on interneurones in the lateral parts of laminae IV–VI and both lateral and medial parts of lamina VII. Some are also distributed to lamina VIII bilaterally. Terminals are also associated with contralateral motor neuronal cell groups in lamina IX, in the dorsolateral group and the lateral parts of both central and ventrolateral groups (Fig. 18.18).

Corticospinal fibres from the frontal cortex, including motor and premotor areas 4 and
6, terminate mostly on interneurones in laminae V–VIII, with the densest concentration ending in the lateral part of lamina VI. They influence α and γ motor neurones of lamina IX, via these interneurones. Because the widespread dendrites of multipolar neurones in lamina IX penetrate lamina VII, direct monosynaptic axodendritic contacts also occur on large α motor neurones. Direct termination on motor neurones is most abundant in the spinal enlargements.

Experimental evidence shows that precentral corticospinal axons influence the activities of both α and γ motor neurones, facilitating flexor muscles and inhibiting extensors, which are the opposite effects to those mediated by lateral vestibulospinal fibres. Evidence from animal studies shows that direct projections from the precentral cortical areas to spinal motor neurones are concerned with highly fractionated, precision movements of the limbs. Accordingly, in primates, precentral corticospinal fibres are mainly distributed to motor neurones supplying the distal limb muscles. Corticospinal projections may use glutamate or aspartate, often co-localized, as excitatory neurotransmitters.

Corticospinal fibres from parietal sources end mainly in the contralateral dorsal horn, in the lateral parts of laminae IV–VI and lamina VII. Phylogenetically these fibres represent the oldest part of the corticospinal system. Axons from the sensory cortex terminate chiefly in laminae IV and V. They are concerned with the supraspinal modulation of the transmission of afferent impulses to higher centres, including the motor cortex.

Experimental studies in primates indicate that isolated transection of corticospinal fibres at the level of the pyramid (pyramidotomy) results in flaccid paralysis or paresis of the contralateral limbs and loss of independent hand and finger movements. Destruction of corticospinal fibres at the level of the internal capsule, commonly caused by a cerebral vascular accident or ‘stroke’, results in a contralateral hemiplegia. The paralysis is initially flaccid, but later becomes spastic, and is most marked in the distal muscles of the extremities, especially those concerned with individual movements of the fingers and hand. Associated signs on the paralysed side are: hyperactive deep tendon reflexes; hypertonicity; the loss of superficial abdominal and cremasteric reflexes; and the appearance of dorsiflexion of the toes (Babinski’s sign) in response to stroking the sole of the foot. The latter is usually interpreted as pathognomonic of corticospinal damage, but it is not always present in patients with confirmed corticospinal lesions. Moreover, Babinski’s sign is normally present in human infants up to about 2 years of age – its subsequent disappearance may reflect the completion of myelination of the corticospinal fibres and/or the establishment of direct cortical connections to lower motor neurones.

Some of the sequelae of stroke damage in the internal capsule, in particular hyperreflexia and hypertonia, are due to the involvement of other pathways in addition to the corticospinal tract. These include descending cortical fibres to brain stem nuclei, such as the vestibular and reticular nuclei, that themselves give rise to descending projections which influence motor neurone activity.

Rubrospinal tract

The rubrospinal tract arises from neurones in the caudal magnocellular part of the red nucleus (an ovoid mass of cells situated centrally in the midbrain tegmentum (p. 290)).
This part of the nucleus contains some 150–200 large neurones, interspersed with smaller neurones.

The origin, localization, termination and functions of rubrospinal connections are poorly defined in man, and the tract appears to be rudimentary. Rubrospinal fibres cross in the ventral tegmental decussation and descend in the lateral funiculus of the cord, where they lie ventral to, and intermingled with, fibres of the lateral corticospinal tract (Fig. 18.9). In animals, the tract descends as far as lumbosacral levels, whereas in man it appears to project only to the upper three cervical cord segments. Rubrospinal fibres are distributed to the lateral parts of laminae V–VI and the dorsal part of lamina VII of the spinal grey matter. The terminal zones of the tract correspond to those of corticospinal fibres from the motor cortex. Animal studies demonstrate that the effects of rubrospinal fibres on α and γ motor neurones are similar to those of corticospinal fibres.

**Tectospinal tract**

The tectospinal tract arises from neurones in the intermediate and deep layers of the superior colliculus of the midbrain. It crosses ventral to the periaqueductal grey matter in the dorsal tegmental decussation and descends in the medial part of the ventral funiculus of the spinal cord (Fig. 18.9). Fibres of the tract project only to the upper cervical cord segments, ending in laminae VI–VIII. They make polysynaptic connections with motor neurones serving muscles in the neck, facilitating those that innervate contralateral muscles and inhibiting those that innervate ipsilateral ones. In animals, unilateral electrical stimulation of the superior colliculus causes turning of the head to the contralateral side, an effect mainly mediated through the tectospinal tract.

**Vestibulospinal tracts**

The vestibular nuclear complex lies in the lateral part of the floor of the fourth ventricle, at the level of the pontomedullary junction. It gives rise to the lateral and medial vestibulospinal tracts, which are functionally and topographically distinct (Fig. 18.19).
The lateral vestibulospinal tract arises from small and large neurones of the lateral vestibular nucleus (Deiters’ nucleus). It descends ipsilaterally, initially in the periphery of the ventrolateral spinal white matter, but subsequently migrating into the medial part of the ventral funiculus at lower spinal levels. Fibres of this tract are somatotopically organized. Thus, fibres projecting to the cervical, thoracic and lumbosacral segments of the cord arise from neurones in the rostroventral, central and dorsocaudal parts, respectively, of the lateral vestibular nucleus. Lateral vestibulospinal fibres end ipsilaterally, mostly in the medial part of the ventral horn in lamina VIII and the medial part of lamina VII. Axons of the lateral vestibulospinal tract are excitatory to motor neurones of extensor muscles of the neck, back and limbs, through both mono- and
polysynaptic connections; γ motor neurones are also probably facilitated. Lateral vestibulospinal tract axons also inhibit motor neurones of flexor limb muscles, via inhibitory interneurones.

The medial vestibulospinal tract (Fig. 18.19) arises mainly from neurones in the medial vestibular nucleus, but some are also located in the inferior and lateral vestibular nuclei. The medial vestibulospinal tract descends in the medial longitudinal fasciculus into the ventral funiculus of the spinal cord where it lies close to the midline in the so-called sulcomarginal fasciculus (Fig. 18.9). Unlike the lateral tract it contains both crossed and uncrossed fibres, and does not extend beyond the midthoracic cord level. Fibres of the medial tract project mainly to the cervical cord segments, ending in lamina VIII and the adjacent dorsal part of lamina VII. Data from stimulation of the vestibular nuclei in animals indicate that axons of the medial tract monosynaptically inhibit the motor neurones that innervate axial muscles of the neck and upper part of the back.

Reticulospinal tracts

The reticulospinal tracts pass from the brain stem reticular formation to the spinal cord. Detailed knowledge of their origins and connections has been obtained mainly from studies in animals.

The medial reticulospinal tract (Fig. 18.16) originates from the medial tegmental fields of the pons and medulla. The main sources are the oral and caudal pontine reticular nuclei and the gigantocellular reticular nucleus in the medulla. Pontine fibres descend, mainly ipsilaterally, in the ventral funiculus of the cord. Medullary fibres descend, both ipsilaterally and contralaterally, in the ventral funiculus and the ventral part of the lateral funiculus. These fibres have many collaterals, and two-thirds of the reticulospinal neurones that reach the cervical cord also descend to lumbosacral levels. The terminals of reticulospinal fibres are distributed to lamina VIII, and the central and medial parts of lamina VII. The medullary reticulospinal terminals are more widely distributed, ending additionally in the lateral parts of laminae VI and VII and also directly on motor neurones. Terminations of reticulospinal fibres that originate in the medulla are, in general, more dorsally placed than those that originate in the pons, although there is considerable overlap.

Both α and γ motor neurones are influenced by reticulospinal fibres, through polysynaptic and monosynaptic connections. Physiological evidence shows that reticulospinal fibres from pontine sources excite motor neurones of axial and limb muscles, while medullary fibres excite, or inhibit motor neurones of cervical muscles and excite motor neurones of axial muscles. Functionally, the medial reticulospinal tract is concerned with posture, the steering of head and trunk movements in response to external stimuli, and crude, stereotyped movements of the limbs.

The lateral reticulospinal tract lies in the lateral funiculus of the spinal cord, closely associated with the rubrospinal and lateral corticospinal tracts (Fig. 18.9). Its fibres arise from neurones of the ventrolateral tegmental field of the pons. The fibres cross in the rostral medulla oblongata and project, with a high degree of collateralization, throughout the length of the spinal cord. Axons of this tract terminate in laminae I, V and VI, and also bilaterally in the lateral cervical nucleus. Evidence suggests that this pathway is involved in the control of pain perception and in motor functions.
Interstitiospinal tract

The interstitiospinal tract arises from neurones in the interstitial nucleus (of Cajal) and the immediate surrounding area, and descends via the medial longitudinal fasciculus into the ventral funiculus of the spinal cord. Its fibres project, mainly ipsilaterally, as far as lumbosacral levels, and are mostly distributed to the dorsal part of lamina VIII and the dorsally adjoining part of lamina VII. They establish some monosynaptic connections with motor neurones supplying neck muscles, but their main connections are disynaptic with motor neurones supplying limb muscles.

Solitariospinal tract

The solitariospinal tract is a small group of mostly crossed fibres which arises from neurones in the ventrolateral part of the nucleus solitarius of the medulla. Descending in the ventral funiculus and ventral part of the lateral funiculus of the cord, these axons terminate on phrenic motor neurones supplying the diaphragm and thoracic motor neurones which innervate intercostal muscles. A pathway with somewhat similar course and terminations to that of the solitariospinal tract originates from the nucleus retroambiguus. Both pathways subserve respiratory activities by driving inspiratory muscles, and some descending axons from the nucleus retroambiguus facilitate expiratory motor neurones. There is clinical evidence that bilateral ventrolateral cordotomy at high cervical levels abolishes rhythmic ventilatory movements.

Hypothalamospinal fibres

Hypothalamospinal fibres exist in animals. They arise from the paraventricular nucleus and other areas of the hypothalamus and descend ipsilaterally, mainly in the dorsolateral region of the cord, to be distributed to sympathetic and parasympathetic preganglionic neurones in the intermediolateral column. Fibres from the paraventricular nucleus show oxytocin and vasopressin immunoreactivity. They are also distributed to laminae I and X. Descending fibres from the dopaminergic cell group (A11) situated in the caudal hypothalamus innervate sympathetic preganglionic neurones and neurones in the dorsal horn. That similar pathways exist in man may be inferred from ipsilateral sympathetic deficits (e.g. Horner's syndrome), which follow lesions of the hypothalamus, the lateral tegmental brain stem, or the lateral funiculus of the cord.

Monoaminergic spinal pathways

Monoaminergic cell groups utilize dopamine, adrenaline (epinephrine), noradrenaline (norepinephrine) and 5-HT (5-hydroxytryptamine, serotonin) as neurotransmitters. They occur widely throughout the brain stem and in the hypothalamus. They project rostrally to many forebrain areas and caudally to the spinal cord and appear to be concerned with the modulation of sensory transmission, and the control of autonomic and somatic motor neuronal activities.

The projections to the spinal cord arise from several sources. Coeruleospinal projections originate from noradrenergic cell groups A4 and A6 in the locus coeruleus complex in the pons and descend via the ventrolateral white matter to innervate all cord segments bilaterally. They end in the dorsal grey matter (laminae IV–VI) and the intermediate and ventral horns. They also project extensively to preganglionic parasympathetic neurones in the sacral cord. Descending noradrenergic fibres, which
arise from the lateral tegmental cell groups A5 and A7 of the pons, travel in the
dorsolateral white matter. They are distributed to laminae I–III, and particularly to the
intermediate grey horn. Descending fibres from adrenergic cell groups C1 and C3 of
the medulla oblongata have been traced into the anterior funiculus of the cord and are
extensively distributed to the intermediolateral column. Dopaminergic fibres projecting
to the spinal cord travel in the hypothalamospinal pathway.

The raphe nuclei pallidus (B1), obscurus (B2) and magnus (B3) in the brain stem give
rise to two serotoninergic descending bundles. The lateral raphe spinal bundle, from
B3 neurones, is concerned with the control of nociception. It descends close to the
lateral corticospinal tract and ends in the dorsal horn (laminae I, II and V). The ventral
bundle, composed mainly of axons from B1 neurones, travels in the medial part of the
ventral white column and ends in the ventral horn (laminae VIII and IX). It facilitates
extensor and flexor motor neurones. Some descending serotoninergic fibres project to
sympathetic preganglionic neurones and are concerned with the central control of
cardiovascular function.

Propriospinal pathways

Propriospinal pathways (fasciculi proprii) consist of the ascending and descending
fibres of intrinsic spinal neurones. They contact other neurones within the same
segment and/or in more distant segments of the spinal cord and so subserve
intrasegmental and intersegmental integration and coordination. The majority of spinal
neurones are propriospinal neurones, most of which lie in laminae V–VIII.
Propriospinal fibres are mainly concentrated around the margins of the grey matter
(Fig. 18.9), but are also dispersed diffusely in the white funiculi.

The propriospinal system plays important roles in spinal functions. Descending
pathways end on specific subgroups of propriospinal neurones and these, in turn,
relay to motor neurones and other spinal neurones. The system mediates all those
automatic functions which continue after transection of the spinal cord, e.g. sudomotor
and vasomotor activities, bowel and bladder functions.

Some propriospinal axons are very short, and span only one segment, while others
run the entire length of the cord. The shortest axons lie immediately adjacent to the
grey matter, and the longer ones are situated more peripherally. Propriospinal
neurones can be categorized according to the length of their axons as long,
intermediate, or short neurones. Long propriospinal neurones distribute their axons
throughout the length of the cord, mainly via the ventral and lateral funiculi; their cell
bodies are in lamina VIII and the dorsally adjoining part of lamina VII. Axons from the
long propriospinal neurones of the cervical cord descend bilaterally, whereas those
from the corresponding lumbosacral neurones ascend mainly contralaterally. Most of
the fibres are fine (less than 3 µm in diameter). Some are the first spinal tract axons to
become myelinated. Intermediate propriospinal neurones occupy the central and
medial parts of lamina VII and project mainly ipsilaterally. Short propriospinal
neurones are found in the lateral parts of laminae V–VIII and their axons run
ipsilaterally in the lateral funiculus.

Propriospinal fibres in the different parts of the white funiculi are distributed
preferentially to specific regions of the spinal grey matter. In the spinal enlargements,
the propriospinal fibres in the dorsolateral funiculus project to the dorsal and lateral
parts of the intermediate zone, and also to spinal motor neurones which supply distal limb muscles, especially those of the hand and the foot. The propriospinal fibres in the ventral part of the ventrolateral funiculus are distributed to the central and medial parts of lamina VII and to motor neurones of proximal limb and girdle muscles. Other propriospinal fibres run in the medial part of the ventral funiculus and travel mainly to the ventromedial part of the intermediate zone, which characteristically contains long propriospinal neurones, and to motor neurones innervating axial and girdle muscles.

**The tract of Lissauer**

The tract of Lissauer, or the dorsolateral tract, lies between the apex of the dorsal horn and the surface of the spinal cord, where it surrounds the incoming dorsal root fibres. It is present throughout the spinal cord, and is most developed in the upper cervical regions.

The tract consists of fine myelinated and non-myelinated axons. Many are the branches of axons in the lateral bundles of the dorsal roots. These axons bifurcate into ascending and descending branches as they enter the cord. The branches travel in the tract of Lissauer for one or two segments and give off collaterals, which end on and around neurones in the dorsal horn. The tract also contains propriospinal fibres, some of which are short axons of small substantia gelatinosa neurones, which re-enter the dorsal horn.
SPINAL CORD LESIONS

Mechanical compression and secondary ischaemic damage to underlying nervous tissue cause surgically relevant spinal cord disease (myelopathy). The site and the level of damage to the cord determine the particular clinical syndrome, e.g. whether the lesion involves the upper or lower cervical, thoracic or lumbosacral spinal cord. At each of these levels, symptoms and signs are determined by direct destruction of segmental tissue, i.e. transversely distributed damage, and disconnection of suprasegmental ascending and descending tracts above and below the level of a lesion, i.e. longitudinally distributed damage (Fig. 18.20). For example, a lower cervical spinal cord lesion damages the segmental sensory and motor contributions to the nerve roots and brachial plexus causing sensory loss, weakness and wasting of the muscles and loss of tendon reflexes in the upper limbs. Disruption of the ascending sensory pathways in the lateral and dorsal columns of the cervical spinal cord leads to loss of sensation to pain and temperature (lateral spinothalamic tracts) and touch and proprioception (dorsal fasciculi) below the ‘sensory level’ corresponding to the segment of the spinal cord.
Damage to the descending corticospinal tracts in the lateral columns of the spinal cord produces a spastic paraparesis, i.e. increased tone of the muscles, weakness of movements of flexion, exaggerated tendon reflexes and abnormal superficial reflexes, e.g. extensor plantar responses and absent abdominal reflexes. Descending pathways to the bladder are interrupted, and this produces a ‘neurogenic bladder’.

The same principles apply to lesions at other levels of the spinal cord and they are illustrated in diagrammatic form in Fig. 18.20.

The precise clinical syndrome is determined by anatomical site alone and not by pathology. However, it is of practical use to classify lesions on the basis of their anatomical relationship to the spinal cord and meninges, i.e. whether they are extradural, intradural or intramedullary (see table). This anatomic classification provides a guide to the diagnostic probabilities as well as an aid to neuroradiological interpretation prior to neurosurgical intervention. For example, neurofibromas are common in the cervical spinal canal, meningiomas in the thoracic spinal canal, and ependymomas in the lumbosacral spinal canal.

Degenerative disease of the vertebral column is common in the cervical and lumbosacral vertebrae, but rare in the thoracic vertebrae. Discrete anterior and central intramedullary lesions, e.g. due to syringomyelia and angiomas respectively, preferentially destroy the spinothalamic pathways in the anterolateral columns and central areas of the spinal cord. This leads to a characteristic ‘dissociated’ sensory loss, i.e. loss of pain and temperature sensation, but with preservation of touch sensation and proprioception at and below the level of the lesion.

CHAPTER 19 – Brain stem

The brain stem consists of the medulla oblongata, pons and midbrain. It is situated in the posterior cranial fossa, and its ventral surface lies on the clivus. It contains numerous intrinsic neuronal cell bodies and their processes, some of which are the brain stem homologues of spinal cell groups. Some brain stem cell groups are the nuclei of cranial nerves III–XII: they are concerned with the sensory, motor and autonomic innervation of the head and neck. Other autonomic fibres that arise from the brain stem are distributed more widely via the vagus nerve. The brain stem also contains a complex and sometimes ill-defined network of neurones, the reticular formation, that extends throughout its length, and is continuous caudally with its spinal counterpart. Some reticular nuclei are referred to as vital centres since they are concerned with regulation of cardiac and respiratory activities; other parts of the reticular formation are essential for cerebral cortical arousal and the maintenance of consciousness, or are involved in the regulation of muscle tone, posture and reflex activities. The brain stem is the site of termination of numerous ascending and descending fibres and is traversed by many others. The spinothalamic tract (spinal lemniscus), medial lemniscus (see Fig. 18.10) and the trigeminothalamic tracts (see Fig. 19.16) all ascend through the brain stem to reach the thalamus Prominent corticospinal projections descend through the brain stem (see Fig. 18.17) and corticobulbar projections end within it.

Damage to the brain stem is often devastating and life-threatening. This is because it is a structurally and functionally compact region, where even small lesions can destroy vital cardiac and respiratory centres, disconnect forebrain motor areas from brain stem and spinal motor neurones, and sever incoming sensory fibres from higher centres of consciousness, perception and cognition. Irreversible cardiac and respiratory arrest follow complete destruction of the neural respiratory and cardiac centres in the medulla. Clinically, this is called brain stem death, a condition that requires accurate diagnosis since it may occur in patients on life-support machines whose respiratory and cardiac functions can be artificially maintained indefinitely.
OVERVIEW OF CRANIAL NERVES AND CRANIAL NERVE NUCLEI

The cranial nerves are the routes by which the brain receives information directly from, and controls the functions of, structures which are located mainly, although not exclusively, within the head and neck. All but two of the twelve pairs of cranial nerves attach to the brain stem. Below is a brief overview of the cranial nerves (consult also Table 15.1), their associated cranial nerve nuclei, and some of the brain stem reflexes to which they contribute. The cranial nerves are described in detail on a regional basis in appropriate chapters.

The cranial nerves are individually named and numbered (using Roman numerals) in a rostro-caudal sequence, reflecting their order of attachment to the brain. The first
cranial nerve (olfactory) terminates directly in cortical and subcortical areas of the frontal and temporal lobes. It is closely associated functionally with the limbic system and is described in that context (Ch. 23). The fibres of the second cranial nerve (optic) pass into the optic chiasma where the centrally located fibres decussate; all of the fibres emerge as the optic tract, which terminates in the lateral geniculate nucleus of the thalamus. Cranial nerves III (oculomotor) and IV (trochlear) attach to the midbrain. Cranial nerve V (trigeminal) attaches to the pons, medial to the middle cerebellar peduncle. Cranial nerves VI (abducens), VII (facial) and VIII (vestibulocochlear) attach to the brain stem at, or close to, the junction of the pons with the medulla. Cranial nerves IX (glossopharyngeal), X (vagus), the cranial part of XI (accessory) and XII (hypoglossal) all attach to the medulla.

Cranial nerves III–XII, which attach to the brain stem, are associated with the brain stem cell groupings referred to collectively as the cranial nerve nuclei (Fig. 19.1). The nuclei are either the origin of efferent cranial nerve fibres or the site of termination of cranial nerve afferents. They are considered to be organized into six discontinuous longitudinal cell columns that correspond to columns that may be identified in the embryo (see Fig. 15.3). Three columns are ‘sensory’ and three are ‘motor’ in function.
The trigeminal sensory nucleus, which extends throughout the length of the brain stem and into the cervical spinal cord, represents a general somatic afferent cell column. Its principal afferents are carried in the trigeminal nerve. General visceral afferents carried by the facial, glossopharyngeal and vagus nerves end in the nucleus solitarius of the medulla. The special somatic afferent column corresponds to the vestibular and cochlear nuclei, which are located beneath the vestibular area of the floor of the fourth ventricle.

The general somatic efferent cell column consists of four nuclei that lie near the midline and give rise to motor fibres which run in nerves of the same name. From rostral to caudal, these are the oculomotor, trochlear and abducens nuclei which innervate the extraocular muscles, and the hypoglossal nucleus, which innervates all but one of the muscles of the tongue. The general visceral efferent, or parasympathetic, cell column is made up of the Edinger–Westphal nucleus of the midbrain, salivary nuclei of the pons, and vagal nucleus of the medulla. Cells in the special visceral efferent column innervate muscles derived from the branchial arches, and lie in the trigeminal motor nucleus, the facial nucleus and the nucleus ambiguus.
MEDULLA OBLONGATA

EXTERNAL FEATURES AND RELATIONS

The medulla oblongata extends from just above the first pair of cervical spinal nerves to the lower border of the pons (Fig. 28.11). It is approximately 3 cm in length and 2 cm in diameter at its widest. The ventral surface of the medulla is separated from the basilar part of the occipital bone and apex of the dens by the meninges and occipito-axial ligaments. Caudally, the dorsal surface of the medulla occupies the midline notch between the cerebellar hemispheres.

The ventral and dorsal surfaces of the medulla (Fig. 19.2, Fig. 19.3) possess a longitudinal median fissure and sulcus, respectively, which are continuous with their spinal counterparts. Caudally, the ventral median fissure is interrupted by the obliquely crossing fascicles of the pyramidal decussation. Rostrally, it ends at the pontine border in a diminutive depression, the foramen caecum. Immediately lateral to the ventral median fissure there is a prominent elongated ridge, the pyramid, which contains descending pyramidal, or corticospinal, axons. The lateral margin of the pyramid is indicated by a shallow ventrolateral sulcus. From this emerges, in line with the ventral spinal nerve roots, a linear series of rootlets which constitute the hypoglossal nerve. The abducens nerve emerges at the slightly narrowed rostral end of the pyramid, where it adjoins the pons. Caudally the pyramid tapers into the spinal ventral funiculus. Lateral to the pyramid and the ventrolateral sulcus there is an oval prominence, the olive (Fig. 19.2), which contains the inferior olivary nucleus. Lateral to the olive is the posterolateral sulcus. The glossopharyngeal, vagus and accessory nerves join the brain stem along the line of this sulcus, in line with the dorsal spinal nerve roots.
Fig. 19.2 Ventral aspect of the brain stem.
The spinal central canal extends into the caudal half of the medulla, migrating progressively more dorsally until it opens out into the lumen of the fourth ventricle. This divides the medulla into a closed part, which contains the central canal, and an open part, which contains the caudal half of the fourth ventricle (Fig. 19.3).

In the closed part of the medulla, a shallow dorsal intermediate sulcus, on either side of the dorsal median sulcus and continuous with its cervical spinal counterpart, indicates the location of the ascending dorsal columns (fasciculus gracilis and fasciculus cuneatus). The ascending fasciculi are at first parallel to each other, but at the caudal end of the fourth ventricle they diverge, and each develops an elongated swelling, the gracile and cuneate tubercles, produced by the subjacent nuclei gracilis and cuneatus respectively (Fig. 19.3, Fig. 19.4, Fig. 19.5). Most fibres in the fasciculi synapse with neurones in their respective nuclei, and these project to the contralateral thalamus, which, in turn, projects to the primary somaesthetic cortex (see Fig. 18.10). The inferior cerebellar peduncle forms a rounded ridge between the caudal part of the fourth ventricle and the glossopharyngeal and vagal rootlets. The peduncles of the two sides diverge and incline to enter the cerebellar hemispheres, where they are crossed by the striae medullares which run to the dorsal median sulcus of the ventricular floor (Fig. 19.3). Here also the peduncles form the anterior and rostral boundaries of the lateral recess of the fourth ventricle. This becomes continuous with the subarachnoid space through the lateral apertures of the fourth ventricle, or
foramina of Luschka. A tuft of choroid plexus, continuous with that of the fourth ventricle, protrudes from the foramina on either side.

Fig. 19.4 Transverse section through the medulla oblongata at the level of the pyramidal decussation. Figs 19.4–19.6, 19.9–19.11, 19.18 and 19.19 are all prepared using a stain for myelinated nerve fibres (blue).
Fig. 19.5 Transverse section through the medulla oblongata at the level of the decussation of the medial lemniscus.
INTERNAL STRUCTURE

Transverse section of the medulla at the level of the pyramidal decussation

A transverse section across the lower medulla oblongata (Fig. 19.4) intersects the dorsal, lateral and ventral funiculi, which are continuous with their counterparts in the spinal cord. The ventral funiculi are separated from the central grey matter by corticospinal fibres, which cross in the pyramidal decussation to reach the contralateral lateral funiculi (see Fig. 19.8). The decussation displaces the central grey matter and central canal dorsally. Continuity between the ventral grey column and central grey matter, which is maintained throughout the spinal cord, is lost. The column subdivides into the supraspinal nucleus (continuous above with that of the hypoglossal nerve), which is the efferent source of the first cervical nerve, and the spinal nucleus of the accessory nerve, which provides some spinal accessory fibres and merges rostrally with the nucleus ambiguus.
The dorsal grey column is also modified at this level as the nucleus gracilis appears as a grey lamina in the ventral part of the fasciculus gracilis. The nucleus begins caudal to the nucleus cuneatus, which invades the fasciculus cuneatus from its ventral aspect in similar fashion.

The spinal nucleus and spinal tract of the trigeminal nerve are visible ventrolateral to the dorsal columns. They are continuous with the substantia gelatinosa and tract of Lissauer of the spinal cord.

*Transverse section of the medulla at the level of the decussation of the medial lemniscus*

The medullary white matter is rearranged above the level of the pyramidal decussation (Fig. 19.5). The pyramids form two large ventral bundles flanking the ventral median fissure on the ventral surface of the medulla.

They contain corticospinal fibres of ipsilateral origin. The nucleus gracilis is prominent on the dorsal aspect, with diminishing numbers of fibres of the fasciculus gracilis located on its dorsal, medial and lateral margins. The nucleus cuneatus is well developed. Both nuclei retain continuity with the central grey matter at this level, but this is lost more rostrally. First-order afferent fibres contained within the fasciculi gracilis and cuneatus synapse upon neurones in their respective nuclei. Second-order axons emerge from the nuclei as internal arcuate fibres, at first curving ventrolaterally around the central grey matter and then ventromedially between the spinal tract of the trigeminal nerve and the central grey matter. The fibres decussate in the midline thereafter forming the medial lemniscus which ascends to the thalamus. The decussation of internal arcuate fibres is located dorsal to the pyramids and ventral to the central grey matter, which is therefore more dorsally displaced than in the previous section.

The medial lemniscus ascends from the decussation as a flattened tract, near the median raphe. The pyramidal tract lies ventrally, and the medial longitudinal fasciculus and the tectospinal tract lie dorsally. Decussating lemniscal fibres are rearranged as they cross, so that those derived from the nucleus gracilis come to lie ventral to those from the nucleus cuneatus. Above this level, the medial lemniscus is further rearranged so that ventral (gracile) fibres migrate laterally, whilst dorsal (cuneate) fibres migrate medially. After such rearrangement, the medial lemniscus is somatotopically organized with C1 to S4 spinal segments represented sequentially from medial to lateral.

The nucleus of the spinal tract of the trigeminal nerve is separated from the central grey matter by internal arcuate fibres, and from the lateral medullary surface by the spinal tract of the trigeminal and by some dorsal spinocerebellar tract fibres. The latter progressively incline dorsally, and enter the inferior cerebellar peduncle at a higher level.

*Transverse section of the medulla at the caudal end of the fourth ventricle*
A transverse section at the lower end of the fourth ventricle (Fig. 19.6) shows some new features together with most of those already described. The total area of grey matter is increased by the presence of the large olivary nuclear complex and nuclei of the vestibulocochlear, glossopharyngeal, vagus and accessory nerves.

**Fig. 19.6** Transverse section through the medulla oblongata at the caudal end of the fourth ventricle.

A smooth, oval elevation, the olive, lies between the ventrolateral and dorsolateral sulci of the medulla. It is formed by the underlying inferior olivary complex of nuclei, and lies lateral to the pyramid, separated from it by the ventrolateral sulcus and emerging hypoglossal nerve fibres. The roots of the facial nerve emerge between its rostral end and the lower pontine border, in the cerebellopontine angle. The arcuate nuclei are curved, interrupted bands, ventral to the pyramids, and are said to be displaced pontine nuclei. Anterior external arcuate fibres and those of the striae medullares are derived from them. They project mainly to the contralateral cerebellum through the inferior cerebellar peduncle (Fig. 19.7).
The inferior olivary nucleus is an irregularly crenated mass of grey matter with a medially directed hilum, through which numerous fibres enter and leave the nucleus. It has prominent connections with the cerebellum and is described more fully in Chapter 20.

The central grey matter at this level constitutes the ventricular floor. It contains (sequentially from medial to lateral): the hypoglossal nucleus, dorsal motor nucleus of the vagus, nucleus solitarius, and the caudal ends of the inferior and medial vestibular nuclei.

The tractus solitarius and the associated nucleus solitarius extend throughout the length of the medulla. The tract is composed of general visceral afferents from the
vagus and glossopharyngeal nerves. The nucleus and its central connections with the reticular formation subserve the reflex control of cardiovascular, respiratory and cardiac functions. The rostral portion of the tract consists of gustatory fibres from the facial, glossopharyngeal and vagal nerves; they project to the rostral pole of the nucleus solitarius, which is sometimes referred to as the gustatory nucleus.

The medial longitudinal fasciculus is a small compact tract near the midline, ventral to the hypoglossal nucleus, that is continuous with the ventral vestibulospinal tract. At this medullary level it is displaced dorsally by the pyramidal and lemniscal decussations. It ascends in the pons and midbrain, maintaining its relationship to the central grey matter and midline, and is therefore near the somatic efferent nuclear column. Fibres from a variety of sources course for short distances in the tract.

Numerous islets of grey matter are scattered centrally in the ventrolateral medulla, an area intersected by nerve fibres that run in all directions. This is the reticular formation, which exists throughout the medulla and extends into the pontine tegmentum and midbrain.

**Pyramidal tract**

Each pyramid contains descending corticospinal fibres, derived from the ipsilateral cerebral cortex, which have traversed the internal capsule, midbrain and pons (Fig. 19.8). Approximately 70–90% of the axons leave the pyramids in successive bundles, crossing in and deep to the ventral median fissure as the pyramidal decussation. In the rostral medulla fibres cross by inclining ventromedially, whereas more caudally they pass dorsally, decussating ventral to the central grey matter. The decussation is orderly, such that fibres destined to end in the cervical segments cross first. Fibres continue to pass dorsally as they descend, and reach the contralateral spinal lateral funiculus as the crossed lateral corticospinal tract. Most uncrossed corticospinal fibres descend ventromedially in the ipsilateral ventral funiculus, as the ventral corticospinal tract. A minority run dorsolaterally to join the lateral corticospinal tracts as a small uncrossed component. The corticospinal tracts display somatotopy at almost all levels. In the pyramids the arrangement is like that at higher levels, in that the most lateral fibres subserve the most medial arm and neck movements. Similar somatotopy is ascribed to the lateral corticospinal tracts within the spinal cord.

**Dorsal column nuclei**

The nuclei gracilis and cuneatus are part of the pathway that is the major route for discriminative aspects of tactile and proprioceptive sensation. The upper regions of both nuclei are reticular and contain small and large multipolar neurones with long dendrites. The lower regions contain clusters of large round neurones with short and profusely branching dendrites. Upper and lower zones differ in their connections but both receive terminals from the dorsal spinal roots at all levels. Dorsal funicular fibres from neurones in the spinal grey matter terminate only in the superior, reticular zone. Variable ordering and overlap of terminals, on the basis of spinal root levels, occur in
both zones. The lower extremity is represented medially, the trunk ventrally, and the
digits dorsally. There is modal specificity, i.e. lower levels respond to low-threshold
cutaneous stimuli, and upper reticular levels to inputs from fibres serving receptors in
the skin, joints and muscles. The cuneate nucleus is divided into several parts. Its
middle zone contains a large pars rotunda, in which rostrocaudally elongated medium-
sized neurones are clustered between bundles of densely myelinated fibres. The
reticular poles of its rostral and caudal zones contain scattered, but evenly distributed,
n neurones of various sizes. The pars triangularis is smaller and laterally placed.

There is a somatotopic pattern of termination of cutaneous inputs from the upper limb
upon the cell clusters of the pars rotunda. Terminations are diffuse in the reticular
poles.

The gracile and cuneate nuclei serve as relays between the spinal cord and higher
levels. Primary spinal afferents synapse with multipolar neurones in the nuclei that
form the major nuclear efferent projection. The nuclei also contain interneurones,
many of which are inhibitory. Descending afferents from the somatosensory cortex
reach the nuclei through the corticobulbar tracts, and appear to be restricted to the
upper, reticular zones. These afferents both inhibit and enhance activity and are
believed to be involved in sensory modulation. The reticular zones also receive
connections from the reticular formation.

Neurones of dorsal column nuclei receive terminals of long, uncrossed, primary
afferent fibres of the fasciculi gracilis and cuneatus, which carry information
concerning deformation of skin, movement of hairs, joint movement and vibration. Unit
recording of the neurones in dorsal column nuclei shows that their tactile receptive
fields (i.e. the skin area in which a response can be elicited) vary in size, although
they are mostly small, and are smallest for the digits. Some fields have excitatory
centres and inhibitory surrounds, which means that stimulation just outside its
excitatory field inhibits the neurone. Neurones in the nuclei are spatially organized into
a somatotopic map of the periphery (in accord with the similar localization in the dorsal
columns). In general, specificity is high. Many cells receive input from one or a few
specific receptor types, e.g. hair, type I and II slowly adapting receptors and Pacinian
corpuscles, and some cells respond to Ia muscle spindle input. However, some
neurones receive convergent input from tactile pressure and hair follicle receptors.

A variety of control mechanisms can modulate the transmission of impulses through
the dorsal column–medial lemniscus pathway. Concomitant activity in adjacent dorsal
column fibres may result in presynaptic inhibition by depolarization of the presynaptic
terminals of one of them. Stimulation of the sensory–motor cortex also modulates the
transmission of impulses by both pre- and postsynaptic inhibitory mechanisms, and
sometimes by facilitation. These descending influences are mediated by the
corticospinal tract. Modulation of transmission by inhibition also results from
stimulation of the reticular formation, raphe nuclei and other sites.

The accessory cuneate nucleus, dorsolateral to the cuneate nucleus, is part of the
spinocerebellar system of precerebellar nuclei (Fig. 19.7). It contains large neurones
like those in the spinal thoracic nucleus and receives the lateral fibres of the fasciculus
cuneatus, which carry proprioceptive impulses from the upper limb that enter the
cervical spinal cord rostral to the thoracic nucleus. The accessory cuneate neurones
give rise to the posterior external arcuate fibres that enter the cerebellum by the
ipsilateral inferior cerebellar peduncle in the cuneocerebellar tract. A group of neurones, nucleus Z, identified in animals between the upper pole of the nucleus gracilis and the inferior vestibular nucleus, is said to be present in the human medulla. Its input is probably from the dorsal spinocerebellar tract, which carries proprioceptive information from the ipsilateral lower limb, and it projects through internal arcuate fibres to the contralateral medial lemniscus.

**Trigeminal sensory nucleus**

The trigeminal sensory nucleus receives the primary afferents of the trigeminal nerve. It is a large nucleus, and extends caudally into the cervical spinal cord and rostrally into the midbrain. The principal and largest division of the nucleus is located in the pontine tegmentum.

On entering the pons, the fibres of the sensory root of the trigeminal nerve run dorsomedially towards the principal sensory nucleus, which is situated at this level (Fig. 19.9). Before reaching the nucleus approximately 50% of the fibres divide into ascending and descending branches – the others ascend or descend without division. The descending fibres, of which 90% are less than 4 µm in diameter, form the spinal tract of the trigeminal nerve, which reaches the upper cervical spinal cord. The tract embraces the nucleus of the spinal tract of the trigeminal (spinal trigeminal nucleus; Fig. 19.4, Fig. 19.5, Fig. 19.6, Fig. 19.10, Fig. 19.11). There is a precise somatotopic organization in the tract. Fibres from the ophthalmic division of the trigeminal lie ventrolaterally, those from the mandibular division lie dorsomedially, and the maxillary fibres lie between them. The tract is completed on its dorsal rim by fibres from the sensory roots of the facial, glossopharyngeal and vagus nerves. All of these fibres synapse in the nucleus caudalis.

**Fig. 19.9** Transverse section of the pons at the level of the trigeminal nerve.
Fig. 19.10 Transverse section through the superior half of the medulla oblongata at the level of the inferior olivary nucleus.

Fig. 19.11 Transverse section through the pons at the level of the facial colliculus.

The detailed anatomy of the spinal tract of the trigeminal excited early clinical interest because it was recognized that dissociated sensory loss could occur in the trigeminal area. For example, in Wallenberg's syndrome, occlusion of the posterior inferior cerebellar branch of the vertebral artery leads to loss of pain and temperature sensation in the ipsilateral half of the face with retention of common sensation. Neurosurgery in this region, as early as the 1890s, attempted to alleviate paroxysmal trigeminal neuralgia. The introduction of medullary tractotomy confirmed that dissociated thermoanalgiesia of the face was associated with destruction of the tract.

There are conflicting opinions on the pattern of termination of the fibres in the spinal nucleus. It has long been held that fibres are organized rostrocaudally within the tract. According to this view, ophthalmic fibres are ventral and descend to the lower limit of the first cervical spinal segment, maxillary fibres are central and do not extend below the medulla oblongata, whilst mandibular fibres are dorsal and do not extend much
below the mid-medullary level. The results of section of the spinal tract in cases of severe trigeminal neuralgia support this distribution. It was found that a section 4 mm below the obex rendered the ophthalmic and maxillary areas analgesic but tactile sensibility, apart from the abolition of ‘tickle’, was much less affected. To include the mandibular area it was necessary to section at the level of the obex. More recently, it has been proposed that fibres are arranged dorsoventrally within the spinal tract. There appear to be sound anatomico-physiological and clinical reasons for believing that all divisions terminate throughout the whole nucleus, although the ophthalmic division may not project fibres as far caudally as the maxillary and mandibular divisions. Fibres from the posterior face (adjacent to C2) terminate in the lower (caudal) part, whilst those from the upper lip, mouth and nasal tip terminate at a higher level. This can give rise to a segmental (cross-divisional) sensory loss in syringobulbia. Tractotomy of the spinal tract, if carried out at a lower level, can spare the perioral region, a finding that would accord with the ‘onion-skin’ pattern of loss of pain sensation. However, in clinical practice, the progression of anaesthesia on the face is most commonly ‘divisional’ rather than onion-skin in distribution.

Fibres of the glossopharyngeal, vagus and facial nerves subserving common sensation (general visceral afferent) form a column dorsally within the spinal tract of the trigeminal nerve and synapse with cells in the lowest part of the spinal trigeminal nucleus. Consequently, operative section of the dorsal part of the spinal tract results in analgesia that extends to the mucosa of the tonsillar sinus, the posterior third of the tongue and adjoining parts of the pharyngeal wall (glossopharyngeal nerve), and the cutaneous area supplied by the auricular branch of the vagus.

Other afferents that reach the spinal nucleus are from the dorsal roots of the upper cervical nerves and from the sensorimotor cortex.

The spinal nucleus is considered to consist of three parts: the subnucleus oralis (which is most rostral and adjoins the principal sensory nucleus); the subnucleus interpolaris; and the subnucleus caudalis (which is the most caudal part and is continuous below with the dorsal grey column of the spinal cord). The structure of the subnucleus caudalis is different from that of the other subnuclei. It has a structure analogous to that of the dorsal horn of the spinal cord, with a similar arrangement of cell laminae, and is involved in trigeminal pain perception. Cutaneous nociceptive afferents and small-diameter muscle afferents terminate in layers I, II, V and VI of the subnucleus caudalis. Low-threshold mechanosensitive afferents of Aβ neurones terminate in layers III and IV of the subnucleus caudalis and rostral (interpolaris, oralis and main sensory) nuclei.

Many of the neurones in the subnucleus caudalis that respond to cutaneous or tooth-pulp stimulation are also excited by stimulation of jaw or tongue muscles. This indicates that convergence of superficial and deep afferent inputs via wide-dynamic-range or nociceptive-specific neurones occurs in the nucleus. Similar convergence of superficial and deep inputs occurs in the rostral nuclei and may account for the poor localization of trigeminal pain, and for the spread of pain, which often makes diagnosis difficult.

There are distinct subtypes of cells in lamina II. Afferents from ‘higher-centres’ arborize within it, as do axons from nociceptive and low-threshold afferents. Descending influences from these higher centres include fibres from the
periaqueductal grey matter and from the nucleus raphe magnus and associated reticular formation.

The nucleus raphe magnus projects directly to the subnucleus caudalis, probably via enkephalin, noradrenaline and 5-HT-containing terminals. These fibres directly or indirectly (through local interneurones) influence pain perception. Stimulation of periaqueductal grey matter or nucleus raphe magnus inhibits the jaw opening reflex to nociception, and may induce primary afferent depolarization in tooth-pulp afferents and other nociceptive facial afferents. Neurones in the subnucleus caudalis can be suppressed by stimuli applied outside their receptive field, particularly by noxious stimuli. The subnucleus caudalis is an important site for relay of nociceptive input and functions as part of the pain ‘gate-control’. However, rostral nuclei also have a nociceptive role. Tooth-pulp afferents via wide-dynamic-range and nociceptive-specific neurones may terminate in rostral nuclei, which all project to the subnucleus caudalis.

Most fibres arising in the trigeminal sensory nuclei cross the midline and ascend in the trigeminal lemniscus. They end in the contralateral thalamic nucleus ventralis posterior medialis, from which third-order neurones project to the cortical postcentral gyrus (areas 1, 2 and 3). However, some trigeminal nucleus efferents ascend to the nucleus ventralis posterior medialis of the ipsilateral thalamus.

Fibres from the subnucleus caudalis, especially from laminae I, V and VI, also project to the rostral trigeminal nuclei, cerebellum, periaqueductal grey of the midbrain, parabrachial area of the pons, the brain stem reticular formation and the spinal cord. Fibres from lamina I project to the subnucleus medius of the medial thalamus.

Vagal nucleus

The vagal nucleus (also known as the dorsal motor nucleus of the vagus) lies dorsolateral to the hypoglossal nucleus, from which it is separated by the nucleus intercalatus. It extends caudally to the first cervical spinal segment and rostrally to the open part of the medulla under the vagal triangle of the floor of the fourth ventricle (Fig. 19.6).

The vagal nucleus is a general visceral efferent nucleus and is the largest parasympathetic nucleus in the brain stem. Most (80%) of its neurones give rise to the preganglionic parasympathetic fibres of the vagus nerve. The remainder are interneurones or project centrally. The vagal nucleus controls the non-striated muscle of the viscera of the thorax (heart, bronchi, lungs and oesophagus) and abdomen (stomach, liver, pancreas, spleen, small intestine and proximal part of the colon). Neurones within the nucleus are heterogeneous and can be classified into nine subnuclei, which are regionally grouped into rostral, intermediate and caudal divisions. Topographic maps of visceral representation in animals suggest that the heart and lungs are represented in the caudal and lateral part of the nucleus, the stomach and pancreas in intermediate regions, and the remaining abdominal organs in the rostral and medial part of the nucleus.

There may be a sparse sensory afferent supply, which arises in the nodose ganglion and projects directly to the nucleus and possibly beyond into the nucleus tractus solitarius.

Hypoglossal nucleus
The prominent hypoglossal nucleus lies near the midline in the dorsal medullary grey matter. It is approximately 2 cm long. Its rostral part lies beneath the hypoglossal triangle in the floor of the fourth ventricle (Fig. 19.3) and its caudal part extends into the closed part of the medulla.

The hypoglossal nucleus consists of large motor neurones interspersed with myelinated fibres. It is organized into dorsal and ventral nuclear tiers, each divisible into medial and lateral subnuclei. There is a musculotopic organization of motor neurones within the nuclei that corresponds to the structural and functional divisions of tongue musculature. Thus, motor neurones innervating tongue retrusor muscles are located in dorsal/dorsolateral subnuclei, whereas motor neurones innervating the main tongue protrusor muscle are located in ventral/ventromedial regions of the nucleus. Although relatively little is known about the organization of motor neurones innervating the intrinsic muscles of the tongue, experimental evidence suggests that motor neurones of the medial division of the hypoglossal nucleus innervate tongue muscles that are oriented in planes transverse to the long axis of the tongue (transverse and vertical intrinsics and genioglossus), whereas motor neurones of the lateral division innervate tongue muscles that are oriented parallel to this axis (styloglossus, hyoglossus, superior and inferior longitudinal).

Several smaller groups of cells lie near the hypoglossal nucleus (perihypoglossal nuclei), but none is known for certainty to be connected with the hypoglossal nerve or nucleus. They include the nucleus intercalatus, sublingual nucleus, nucleus prepositus hypoglossi and nucleus paramedianus dorsalis (reticularis). Gustatory and visceral connections are attributed to the nucleus intercalatus.

Hypoglossal fibres emerge ventrally from their nucleus, traverse the reticular formation lateral to the medial lemniscus, pass medial to (sometimes through) the inferior olivary nucleus, and curve laterally to emerge as a linear series of 10–15 rootlets in the ventrolateral sulcus between the pyramid and olive.

The hypoglossal nucleus receives corticobulbar fibres from the precentral gyrus and adjacent areas of (mainly) the contralateral hemisphere. They either synapse on motor neurones of the nucleus directly or on interneurones. Evidence indicates that the most medial hypoglossal subnuclei receive projections from both hemispheres. The nucleus may connect with the cerebellum via adjacent perihypoglossal nuclei, and perhaps also with the medullary reticular formation, the trigeminal sensory nuclei and the solitary nucleus.

**Inferior olivary nucleus**

The olivary nuclear complex consists of the large inferior olivary nucleus and the much smaller medial accessory and dorsal accessory olivary nuclei (Fig. 19.6). They are the so-called precerebellar nuclei, a group that also includes the pontine, arcuate, vestibular, reticulocerebellar and spinocerebellar nuclei, all of which receive afferents from specific sources and project to the cerebellum. The inferior olivary nucleus contains small neurones, most of which form the olivocerebellar tract, which emerges either from the hilum or through the adjacent grey matter, to run medially and intersect the medial lemniscus (Fig. 19.6). Its fibres cross the midline, and sweep either dorsal to, or through, the opposite olivary nucleus. They intersect the lateral spinothalamic
and rubrospinal tracts and the spinal trigeminal nucleus, and enter the contralateral inferior cerebellar peduncle, where they constitute its major component. Fibres from the contralateral inferior olivary complex terminate on Purkinje cells in the cerebellum as climbing fibres – there is a one-to-one relationship between Purkinje cells and neurones in the complex. Afferent connections to the inferior olivary nucleus are both ascending and descending. Ascending fibres, mainly crossed, arrive from all spinal levels in the spino-olivary tracts and via the dorsal columns. Descending ipsilateral fibres come from the cerebral cortex, thalamus, red nucleus and central grey of the midbrain. In part the two latter projections make up the central tegmental tract (fasciculus).

The medial accessory olivary nucleus is a curved grey lamina, concave laterally, between the medial lemniscus and pyramid and the ventromedial aspect of the inferior olivary nucleus. The dorsal accessory olivary nucleus is a similar lamina, dorsomedial to the inferior olivary nucleus. Both nuclei are connected to the cerebellum. The accessory olivary nuclei are phylogenetically older than the inferior olivary nucleus, and they are connected with the paleocerebellum. In all connections, cerebral, spinal and cerebellar, the olivary nuclei display specific topographical organization (Ch. 20).

**Nucleus solitarius**

The nucleus solitarius (solitary nucleus, nucleus of the solitary tract) lies ventrolateral to the vagal nucleus and is almost coextensive with it. A neuronal group ventrolateral to the nucleus solitarius has been termed the nucleus parasolitarius. The nucleus solitarius is intimately related to, and receives fibres from, the tractus solitarius, which carries afferent fibres from the facial, glossopharyngeal and vagus nerves. These fibres enter the tract in descending order and convey gustatory information from the lingual and palatal mucosa. They may also convey visceral impulses from the pharynx (glossopharyngeal and vagus) and from the oesophagus and abdominal alimentary canal (vagus). There is some overlap in this vertical representation.

Termination of special visceral gustatory afferents within the nucleus shows a viscerotopic pattern, predominantly in the rostral region. Experimental evidence suggests that fibres from the anterior two-thirds of the tongue and the roof of the oral cavity (which travel via the chorda tympani and greater petrosal branches of the facial nerve) terminate in the extreme rostral part of the solitary complex. Those from the circumvallate and foliate papillae of the posterior third of the tongue, tonsils, palate and pharynx (which travel via the lingual branch of the glossopharyngeal nerve) are distributed throughout the rostrocaudal extent of the nucleus, predominantly rostral to the obex. Gustatory afferents from the larynx and epiglottis (which travel via the superior laryngeal branch of the vagus) have a more caudal and lateral distribution. The nucleus solitarius may also receive fibres from the spinal cord, cerebral cortex and cerebellum.

Medial and commissural subnuclei in the caudal part of the nucleus appear to be the primary site of termination for gastrointestinal afferents. Ventral and interstitial subnuclei probably receive tracheal, laryngeal and pulmonary afferents and play an important role in both respiratory control and possibly rhythm generation. The carotid sinus and aortic body nerves terminate in the dorsal and dorsolateral region of the nucleus solitarius, which may be involved in cardiovascular regulation.
The nucleus solitarius is thought to project to the sensory thalamus and thence to the cerebral cortex. It may also project to the upper levels of the spinal cord through a solitariospinal tract. Secondary gustatory axons cross the midline. Many subsequently ascend the brain stem in the dorsomedial part of the medial lemniscus and synapse on the most medial neurones of the thalamic nucleus ventralis posterior medialis (in a region sometimes termed the accessory arcuate nucleus). Axons from the nucleus ventralis posterior medialis radiate through the internal capsule to the anteroinferior area of the sensorimotor cortex and the insula. It is thought that other ascending paths end in a number of the hypothalamic nuclei, and so mediate the route by which gustatory information may reach the limbic system and allow appropriate autonomic reactions to be made.

**Swallowing and gag reflexes**

During the normal processes of eating and drinking, passage of material to the rear of the mouth stimulates branches of the glossopharyngeal nerve in the oropharynx (Fig. 19.12). This information is relayed via the nucleus solitarius to the nucleus ambiguus, which contains the motor neurones innervating the muscles of the palate, pharynx, and larynx. The nasopharynx is closed off from the oropharynx by elevation of the soft palate. The larynx is raised, its entrance narrowed and the glottis is closed. Peristaltic activity down the oesophagus to the stomach is mediated through the pharyngeal plexus.
If stimulation of the oropharynx occurs, other than during swallowing, the gag reflex may be initiated. There is a reflex contraction of the muscles of the pharynx, soft palate, and fauces that, if extreme, may result in retching and vomiting.

**Nucleus ambiguus**

The nucleus ambiguus is a group of large motor neurones, situated deep in the medullary reticular formation (see Fig. 19.10). It extends rostrally as far as the upper end of the vagal nucleus while caudally it is continuous with the nucleus of the spinal accessory nerve. Fibres emerging from it pass dorsomedially, then curve laterally. Rostral fibres join the glossopharyngeal nerve. Caudal fibres join the vagus and cranial accessory nerves and are distributed to the pharyngeal constrictors, intrinsic laryngeal muscles and striated muscles of the palate and upper oesophagus.

The nucleus ambiguus contains several cellular subgroups, and some topographical representation of the muscles innervated has been established. Individual laryngeal muscles are innervated by relatively discrete groups of cells in more caudal zones. Neurones that innervate the pharynx lie in the intermediate area, and neurones that innervate the oesophagus and soft palate are rostral.

The nucleus ambiguus receives corticobulbar fibres bilaterally and is connected to many brain stem centres. At its upper end, a small retrofacial nucleus intervenes between it and the facial nucleus. Although the nucleus ambiguus is generally regarded as a special visceral efferent nucleus, it is also a reputed source of general visceral efferent fibres to the vagus.

**Cough and sneeze reflexes**

Irritation of the larynx or trachea is conveyed via laryngeal branches of the vagus nerve to the trigeminal sensory nucleus of the brain stem. Impulses are relayed to medullary respiratory centres and to the nucleus ambiguus. Forceful exhalation (coughing) occurs, caused by contraction of intercostal and abdominal wall muscles after a build-up of pressure against an initially closed glottis.

A similar mechanism underlies sneezing (Fig. 19.13) except that the stimulus arises from the nasal mucosa and afferent impulses are conveyed by the ophthalmic or maxillary divisions of the trigeminal nerve to the trigeminal sensory nucleus. After sharp inhalation, explosive exhalation occurs with closure of the oropharyngeal isthmus by the action of palatoglossus, which diverts air through the nasal cavity.
Fig. 19.13 Sneeze and cough reflexes.
PONS

EXTERNAL FEATURES AND RELATIONS

The pons lies rostral to the medulla and caudal to the midbrain. On the ventral surface of the brain stem, the transition between medulla and pons is clearly demarcated by a transverse sulcus. Laterally, in a region known as the cerebellopontine angle, the facial, vestibulocochlear and glossopharyngeal nerves emerge. The ventral surface of the pons is separated from the clivus (basisphenoid and dorsum sellae) by the cisterna pontis. It is markedly convex transversely, less so vertically, and grooves the petrous part of the temporal bone laterally up to the internal acoustic meatus. The surface has a shallow median sulcus, in which the basilar artery runs, bounded bilaterally by prominences that are formed partly by underlying corticospinal fibres as they descend through the pons. Bundles of transverse fibres, bridging the midline and originating from nuclei in the basal pons (nuclei pontis, pontine nuclei), converge on each side into the large middle cerebellar peduncle and project to the cerebellum. The trigeminal nerve emerges near the midpontine level. It has a small superomedial motor root and a large inferolateral sensory root.

The dorsal surface of the pons is hidden by the cerebellum which covers the rostral half of the rhomboid fossa, into which the aqueduct of the midbrain empties. The roof of the fossa is formed by a thin sheet of tissue, the superior (anterior) medullary velum, and is overlain by the lingula of the vermis of the cerebellum. The velum is attached on each side to the superior cerebellar peduncles and is enclosed by pia mater above and ependyma below (Fig. 19.3). The trochlear nerves decussate in the velum.
INTERNAL STRUCTURE

**Transverse sections of the pons**

Transverse sections (Fig. 19.9, Fig. 19.11) reveal that the pons consists of a dorsal tegmentum, which is a continuation of the medulla (excluding the pyramids), and a ventral (basilar) part. The latter contains bundles of longitudinal descending fibres, some of which continue into the pyramids, while others end in the many pontine or medullary nuclei. It also contains numerous transverse fibres and scattered pontine nuclei.

**Ventral pons**

The ventral pons is similar in structure at all levels. The longitudinal fibres of the corticopontine, corticobulbar and corticospinal tracts descend from the crus cerebri of the midbrain and enter the pons compactly. They rapidly disperse into fascicles, which are separated by the pontine nuclei and transverse pontine fibres. Corticospinal fibres run uninterrupted through the pons to the medullary pyramids, where they again converge into compact tracts. Corticobulbar fibres terminate in contralateral (and some ipsilateral) nuclei of cranial nerves and other nuclei in the pontine tegmentum. Clinical evidence supports the view that the neurones of the facial nucleus, and in particular, those serving the muscles of the upper face, receive bilateral cortical control.

The pontine nuclei (Fig. 19.11) include all the neurones (in man, some 20 million) that are scattered throughout the ventral pons. They are probably all glutamatergic, and most project to the contralateral cerebellar cortex, with some input to the deep cerebellar nuclei. Efferent axons from the pontine nuclei constitute the transverse pontine (pontocerebellar) fibres which decussate and continue as the major constituent of the contralateral middle cerebellar peduncle. All pontocerebellar fibres end as mossy fibres in the cerebellar cortex, and a degree of somatotopy is maintained in these connections.

Corticopontine fibres, from the frontal, temporal, parietal and occipital cortices, end upon neurones in the pontine nuclei. Frontopontine fibres end rostral to the level of the trigeminal nerve, and connect with pontine neurones which project to the contralateral cerebellum in the more rostral transverse pontine fibres. Corticopontine fibres arise mainly from neurones in layer V of the premotor, somatosensory, posterior parietal, extrastriate visual and cingulate neocortices. Projections from prefrontal, temporal and striate cortices are sparse. The terminal fields, although divergent, form topographically segmented patterns resembling overlapping columns, slabs or lamellae within the pons.

Subcortical projections to the pontine nuclei include those from the superior colliculus to the dorsolateral pons, and the medial mammillary nucleus to the rostromedial pons and pretectal nuclei. The lateral geniculate nucleus, dorsal column nuclei, trigeminal nuclei, hypothalamus and intracerebellar nuclei also project to restricted neurones of the pons. Functionally related subcortical and cerebrocortical afferents converge, e.g. those from the somatosensory cortex and dorsal column nuclei. There is also non-specific input from the reticular formation, raphe nuclei, locus coeruleus and paraqueductal grey matter.
**Pontine tegmentum**

The pontine tegmentum varies in cytoarchitecture at different levels. A transverse section through the lower pontine tegmentum transects the facial colliculus in the floor of the fourth ventricle (Fig. 19.11, Fig. 19.14). The colliculus contains the nucleus of the abducens nerve and the overlying fibres of the facial nerve. More deeply placed are the facial nuclei, the nearby vestibular and cochlear nuclei and other isolated neuronal groups. The vestibular nuclei are laterally placed in the rhomboid fossa of the fourth ventricle, subjacent to the vestibular area, which spans the rostral medulla and caudal pons (Fig. 19.1, Fig. 19.3).
The striae medullares of the fourth ventricle (Fig. 19.10) are an aberrant cerebropontocerebellar connection, in which the arcuate nuclei and external arcuate fibres are involved. Axons from arcuate nuclei spread round the medulla, above and below the inferior olive, where they are superficially visible as the circumolivary fasciculus. All these fibres, which collectively are known as the external arcuate fibres, enter the inferior cerebellar peduncle (Fig. 19.7). Some fibres from arcuate nuclei pass dorsally through the medulla near its midline, decussate near the floor of the fourth ventricle, then turn laterally under the ependyma and enter the cerebellum through the inferior peduncle.

In addition to the tracts already noted at lower levels, the lower pontine tegmentum contains the trapezoid body, lateral lemniscus and emerging fibres of the abducens and facial nerves. The medial lemniscus is ventral, its transverse outline now a flat oval. It extends laterally from the median raphe (Fig. 19.9, Fig. 19.11) and is laterally related to the lateral spinothalamic tract and trigeminal lemniscus. The fibres of the latter originate from neurones of the contralateral spinal nucleus, serving pain and thermal sensibility in facial skin and mucosae of the conjunctiva, tongue, mouth, nose, etc. Here the lemnisci together form a transverse band which is composed, in lateral order from the midline, of the medial and trigeminal lemnisci, the lateral spinothalamic tract and the lateral lemniscus.

The trapezoid body contains cochlear fibres, mainly from the ventral cochlear and trapezoid nuclei. They ascend transversely in the ventral tegmentum, pass either through or ventral to the vertical medial lemniscal fibres, and decussate with the contralateral fibres in the median raphe. Below the emerging facial axons, the trapezoid fibres turn up into the lateral lemniscus. As the lateral lemniscus ascends it lies near the dorsolateral surface of the brain stem. Above, its fibres enter the inferior colliculus and medial geniculate body. The ascending auditory pathway is described in detail in Chapter 37.

The medial longitudinal fasciculus is paramedian, ventral to the fourth ventricle, near the abducens nucleus from which it is separated by facial nerve fibres. It is the main intersegmental tract in the brain stem, particularly for interactions between nuclei of cranial nerves innervating the extraocular muscles and the vestibular system. In the lower pons it receives fibres from vestibular, and perhaps dorsal trapezoid, nuclei. Its greater part is formed by vestibular contributions.

A transverse section at an upper pontine tegmental level contains trigeminal elements...
(Fig. 19.9), but otherwise shows little notable alteration from a section through a lower pontine tegmental level. Its dorsolateral parts are invaded by the superior cerebellar peduncles. The small nucleus of the lateral lemniscus, a relay in the auditory pathway, lies medial to its tract in the upper pons, and receives some lemniscal terminals. Some of its efferent fibres enter the medial longitudinal fasciculus, others return to the lemniscus.

The medial lemniscus (Fig. 19.9, Fig. 19.11) retains its paramedian position in the ventral pontine tegmentum, where it lies a little lateral to the median raphe, and is joined medially by fibres from the principal trigeminal sensory nucleus. The trigeminal lemniscus, lateral spinothalamic tract, and the lateral lemniscus and its nucleus all lie dorsolaterally.

Cochlear nuclei

Fibres of the cochlear division of the vestibulocochlear nerve partially encircle the inferior cerebellar peduncle laterally and end in the dorsal and ventral cochlear nuclei. The dorsal cochlear nucleus forms a bulge, the auditory tubercle, on the posterior surface of the peduncle, and is continuous medially with the vestibular area in the rhomboid fossa. The ventral cochlear nucleus is ventrolateral to the dorsal cochlear nucleus, and lies between the cochlear and vestibular fibres of the vestibulocochlear nerve.

Cochlear nerve fibres, which are derived from neuronal somata in the spiral ganglion, bifurcate on entering the brain stem and terminate in both dorsal and ventral cochlear nuclei (see Fig. 37.20).

The ventral cochlear nucleus has a complex cytoarchitecture. It contains many neuronal types with distinct dendritic field characteristics. Marked topographical order has been demonstrated in cochlear nerve terminals within the nucleus. Different parts of the spiral ganglion and differing stimulation frequencies are related to neurones that are serially arrayed anteroinferiorly in the ventral nucleus. All cochlear nerve fibres enter the nucleus. There are approximately 25,000 axons in the human cochlear nerve, and they project onto a much larger number of neurones in the cochlear nucleus. The number of cochlear fibres in the lateral lemniscus greatly exceeds that in the cochlear nerve. A minor fraction of the cochlear neurones receive terminals from the nerve, though each fibre may connect with several neurones. Terminals are limited to the anteroinferior region of the ventral nucleus, where the neurones are probably mostly local interneurones.

The dorsal cochlear nucleus is almost continuous with the ventral nucleus, from which it is only separated by a thin stratum of nerve fibres. Giant cells predominate, and their dendritic fields are aligned with the incoming auditory fibres.

Though the cellular origins are not precisely known, axons of most neuronal types in the cochlear nuclei leave to end at pontine levels in the superior olivary, trapezoid and lateral lemniscal nuclei (Fig. 19.9). They leave the cochlear nuclei by three routes. The largest group of axons lies ventrally and decussates as the trapezoid body, level with the pontomedullary junction (Fig. 19.9, Fig. 19.11). Most of these axons ascend slightly, decussate and relay in the contralateral nuclei. A few do not cross, and synapse in the ipsilateral superior olivary nuclei. From both nuclei, the next order
axons ascend in the corresponding lateral lemniscus. Occasional decussating fibres traverse the contralateral superior olive and enter the lateral lemniscus to relay in lemniscal nuclei.

Some axons from ventral cochlear neurones pass dorsally, superficial to descending trigeminal spinal fibres, cerebellar fibres in the inferior peduncle, and axons of the dorsal cochlear nucleus. This bundle of ventral cochlear fibres is smaller than that of the trapezoid decussation. It swerves ventromedially across the midline, ventral to the medial longitudinal fasciculus, as the intermediate acoustic striae. Its further path is uncertain, but it probably ascends in the contralateral lateral lemniscus.

The most dorsally placed axons issue from the dorsal cochlear nucleus. They curve dorsomedially round the inferior cerebellar peduncle towards the midline as the dorsal acoustic striae, ventral to the striae medullares. They incline ventromedially and cross the midline to ascend in the contralateral lateral lemniscus, probably relaying in its nuclei.

The superior olivary complex is sited in the tegmentum of the caudal pons, lateral in the reticular formation at the level of the pontomedullary junction. The superior complex includes several named nuclei and nameless smaller groups. In humans, the lateral superior olivary nucleus is made up of some six small cellular clusters. The medial (accessory) superior olivary nucleus is large and compact. The trapezoid nucleus is medial. A retro-olivary group, the reputed origin of some efferent cochlear fibres, is dorsal. Some internuclear connections have been described. The medial superior olivary nucleus receives impulses from both spiral organs, and may be involved in sound source localization. The superior olivary complexes and the trapezoid nuclei are relay stations in the ascending auditory projection. These intricate connections have not been well established in man.

The medial nucleus of the trapezoid body is small in man. It has a ventral component, which consists of large neurones scattered among the trapezoid fascicles, and a more compact dorsal nucleus, medial to the superior olivary complex. The nucleus lies at the level of the exiting abducens nerve roots, anterior to the central tegmental tract. It is not known whether the human trapezoid nuclei function in the auditory relay. Some trapezoid axons may enter the medial longitudinal fasciculus, and ascend to end in trigeminal, facial, oculomotor, trochlear and abducens nuclei, where they mediate reflexes involving tensor tympani, stapedius and oculogyric muscles, respectively.

The nucleus of the lateral lemniscus consists of small groups of neurones (counts of 18,000 to 24,000 have been recorded in humans) that lie among the fibres of the lateral lemniscus. Dorsal, ventral and intermediate groups probably receive afferent axons from both cochlear nuclei. Their efferents enter the midbrain along the lateral lemniscus and terminate in the inferior colliculi.

Some efferent axons travel in the cochlear nerves to the spiral organ. Though few in number, they may be involved in hearing, perhaps by modulating sensory transduction through reflexes via cochlear nuclei. The neurones of origin are located at the hilus and along the lateral border of the lateral superior olivary nucleus and lateral edge of the ventral trapezoid nucleus. Fibres from both sides proceed to both cochleae.
Vestibular nuclei

The vestibular complex consist of the medial, lateral (Deiters’ nucleus), superior and inferior vestibular nuclei. The medial vestibular nucleus is the largest. It broadens, then narrows as it ascends from the upper olivary level into the lower pons, where it separates the vagal nucleus from the floor of the fourth ventricle. It is crossed by the striae medullares, running nearer the floor, and is continuous with the nucleus intercalates below. The inferior vestibular nucleus (which is the smallest) lies between the medial vestibular nucleus and inferior cerebellar peduncle, from the level of the upper end of the nucleus gracilis to the pontomedullary junction. It is crossed by descending fibres of the vestibulocochlear nerve and the vestibulospinal tract. The lateral vestibular nucleus lies just above the inferior nucleus and is ventrolateral to the upper part of the medial nucleus. It ascends almost to the level of the abducens nucleus and its rostral end is continuous with the caudal end of the superior nucleus. The lateral vestibular nucleus is composed of large multipolar neurones, which are the main source of the vestibulospinal tract. The superior vestibular nucleus is small and lies above the medial and lateral nuclei. It extends higher into the pons than other subdivisions, and occupies the upper part of the vestibular area.

Through its connections, the vestibular system influences movements of the eyes and head, and of the muscles of the trunk and limbs, in order to maintain equilibrium. The vestibular nuclei receive fibres from the vestibular part of the vestibulocochlear nerve, cerebellum, brain stem reticular formation and spinal cord. They send axons to the cerebellum, medial longitudinal fasciculus, spinal cord and lateral lemniscus. Evidence suggests that the vestibular apparatus is spatially represented in the nuclei. Vestibular fibres of the vestibulocochlear nerve enter the medulla between the inferior cerebellar peduncle and the trigeminal spinal tract, and approach the vestibular area, where they bifurcate into descending and ascending branches. The former descend medial to the inferior cerebellar peduncle and end in medial, lateral and inferior vestibular nuclei, and the latter enter the superior and medial nuclei. A few vestibular fibres enter the cerebellum directly through the inferior peduncle (superficially in the juxtarestiform body), and end in the fastigial nucleus, flocculonodular lobe and uvula.

The vestibular nuclei project extensively to the cerebellum and also receive axons from the cerebellar cortex and the fastigial nuclei. Vestibulocerebellar fibres travel via the inferior cerebellar peduncle mainly to the flocculus and nodule. Cerebellovestibular fibres pass to the nuclei, also through the inferior cerebellar peduncle. They arise mainly in the flocculus and nodule (posterior lobe), but some fibres are derived from the anterior lobe and fastigial nucleus. The vestibular nuclear complex projects to the pontine reticular nuclei and to motor nuclei of the oculogyric muscles in the medial longitudinal fasciculus. The complex also projects to the spinal cord via the vestibulospinal tracts and the medial longitudinal fasciculus (see Fig. 18.19).

Information from the vestibular nuclei also reaches the cerebral cortex by way of the thalamus (probably via posterior parts of the ventroposterior complex and the medial pulvinar). The primary vestibular cortical area is located in the parietal lobe at the junction between the intraparietal and the postcentral sulci, which is adjacent to that portion of the postcentral gyrus where the head is represented. This makes sense functionally because this region of the somatosensory cortex is concerned with conscious appreciation of body position. There may be an additional representation of
the vestibular system in the superior temporal gyrus near the auditory cortex.

Abducens nucleus

The abducens nucleus is a group of approximately 6500 neurones, occupying a paramedian position in the central grey matter, in line with the trochlear, oculomotor and hypoglossal nuclei, with which it forms a somatic motor column (Fig. 19.1). It lies ventromedial to the medial longitudinal fasciculus, which is the means by which vestibular, cochlear and other cranial nerve nuclei, especially the oculomotor, connect with the abducens. The abducens nucleus contains large motor neurones and small multipolar interneurones, which are intermixed, although the latter are most heavily concentrated in its lateral and ventral aspects. Axons from the motor neurones cross the midline at the level of the nucleus and ascend in the medial longitudinal fasciculus to all three medial rectus subnuclei of the oculomotor nucleus.

Efferent abducens axons pass ventrally, descend through the reticular formation, trapezoid body and medial lemniscus, and traverse the ventral pons to emerge at its inferior border (Fig. 19.14): they innervate the lateral rectus muscle (see Ch. 39).

The abducens nucleus receives afferent connections from corticobulbar fibres (which are principally contralateral, some of the fibres being aberrant corticospinal fibres that descend from the midbrain to this level in the medial lemniscus); the medial longitudinal fasciculus (by which it is connected to oculomotor, trochlear and vestibular nuclei); the tectobulbar tract (from the deep layers of the superior colliculus); the paramedian pontine reticular formation (which lies rostral and caudal to the nucleus); the nucleus prepositus hypoglossi; and the contralateral medullary reticular formation.

Facial nucleus

The facial (motor) nucleus lies in the caudal pontine reticular formation, posterior to the dorsal trapezoid nucleus and ventromedial to the trigeminal spinal tract and nucleus. Groups of facial neurones form columns, which innervate individual muscles or which correspond to branches of the facial nerve. Neurones innervating muscles in the scalp and upper face are dorsal, and those supplying the lower facial musculature are ventral.

Efferent fibres of the large motor neurones of the facial nucleus form the motor root of the facial nerve. The motor nucleus represents the branchial efferent column, but it lies much more deeply in the pons than might be expected, and its axons have a most unusual course (Fig. 19.14). At first they incline dorsomedially towards the fourth ventricle, below the abducens nucleus, and ascend medial to it, near the medial longitudinal fasciculus. They then curve round the upper pole of the abducens nucleus and descend ventrolaterally through the reticular formation. Finally, they pass between their own nucleus medially and the spinal trigeminal nucleus. They emerge between the olive and the inferior cerebellar peduncle at the cerebellopontine angle.

The facial nucleus receives corticobulbar fibres for volitional control. Neurones that innervate muscles in the scalp and upper face are believed to receive bilateral corticobulbar fibres, while those supplying lower facial musculature only receive a contralateral innervation. Clinically, upper and lower motor neurone lesions of the facial nerve can be differentiated because the former results in paralysis that is confined to the contralateral lower face, whilst the latter results in a complete
ipsilateral paralysis (Bell's palsy).

The facial nucleus also receives ipsilateral afferents from the nucleus solitarius and from the trigeminal sensory nucleus, establishing important reflex connections.

Some efferent fibres of the facial nerve originate from neurones in the superior salivatory nucleus, which is said to be in the reticular formation dorsolateral to the caudal end of the facial nucleus. These preganglionic parasympathetic neurones belong to the general visceral efferent column. They send fibres into the sensory root of the facial nerve. These travel via the chorda tympani to the submandibular ganglion and via the greater petrosal nerve and the nerve of the pterygoid canal to reach the pterygopalatine ganglion.

Corneal reflex

Touching the cornea or shining a bright light into the eye elicits reflex closure of both eyes. The former action stimulates nasociliary branches of the ophthalmic nerve, and the latter stimulates the retina and optic pathway. In both cases, afferent impulses enter the central nervous system and spread via interneurones to activate neurones in the facial motor nucleus in the pons (Fig. 19.15). Efferent impulses travel in the facial nerve to activate the palpebral component of orbicularis oculi, which contracts, producing a ‘blink’. The sweep of the eyelids carries lacrimal secretions across the eye helping to remove any irritating particles.

![Corneal reflex](image_url)

Fig. 19.15 Corneal reflex. Unilateral stimulation of the cornea elicits a bilateral corneal reflex (not illustrated).

Trigeminal sensory nucleus

On entering the pons, the fibres of the sensory root of the trigeminal nerve run dorsomedially towards the principal sensory nucleus (Fig. 19.9). About 50% of the
fibres divide into ascending and descending branches; the others ascend or descend without division. The descending fibres form the spinal tract of the trigeminal, which terminates in the subjacent nucleus of the spinal tract (spinal nucleus) of the trigeminal nerve.

Some ascending trigeminal fibres, many of them heavily myelinated, synapse around the small neurones in the principal sensory nucleus (Fig. 19.16), which lies lateral to the motor nucleus and medial to the middle cerebellar peduncle, and is continuous inferiorly with the spinal nucleus. The principal nucleus is considered to be mainly concerned with tactile stimuli.

Other ascending fibres enter the mesencephalic nucleus, a column of unipolar cells whose peripheral branches may convey proprioceptive impulses from the masticatory muscles, and possibly also from the teeth and the facial and oculogyric muscles. Its neurones are unique in being the only primary sensory neurones with somata in the CNS. It is the relay for the ‘jaw jerk’, which is the only significant supraspinal monosynaptic reflex. Nerve fibres that ascend to the mesencephalic nucleus may give collaterals to the motor nucleus of the trigeminal nerve and to the cerebellum.

**Jaw jerk reflex**

Rapid stretching of the muscles that close the jaw (masseter, temporalis, medial pterygoid) activates muscle spindle afferents, which travel via the mandibular division of the trigeminal nerve to the brain stem (Fig. 19.17). The cell bodies of these primary afferent neurones are located in the mesencephalic nucleus of the trigeminal. Collaterals project monosynaptically to the motor nucleus of the trigeminal nerve in the pons. From here motor axons of the mandibular nerve innervate the muscles that close the jaw.

![Fig. 19.17 Jaw jerk reflex.](image)

Most fibres that arise in the trigeminal sensory nuclei cross the midline and ascend in the trigeminal lemniscus. They end in the contralateral thalamic nucleus ventralis.
posterior medialis, from which third-order neurones project to the cortical postcentral gyrus (areas 1, 2 and 3). Some trigeminal nucleus efferents ascend to the nucleus ventralis posterior medialis of the ipsilateral thalamus.

**Trigeminal motor nucleus**

The trigeminal motor nucleus is ovoid in outline and lies in the upper pontine tegmentum, under the lateral part of the floor of the fourth ventricle (Fig. 19.1). It lies medial to the principal sensory nucleus, and is separated from it by fibres of the trigeminal nerve. It occupies the position of the branchial (special visceral) efferent column.

The motor nucleus contains characteristic large multipolar neurones interspersed with smaller multipolar cells. The neurones are organized into a number of relatively discrete subnuclei, the axons from which innervate individual muscles. It receives fibres from both corticobulbar tracts. These fibres leave the tracts at the nuclear level or higher in the pons (aberrant corticospinal fibres), and descend in the medial lemniscus. They may end on motor neurones or interneurones. The motor nucleus receives afferents from the sensory nuclei of the trigeminal nerve, possibly including some from the mesencephalic nucleus, which form monosynaptic reflex arcs for proprioceptive control of the masticatory muscles. It also receives afferents from the reticular formation, red nucleus and tectum, the medial longitudinal fasciculus and possibly from the locus coeruleus. Collectively these represent pathways by which salivary secretion and mastication may be coordinated.

**Tensor tympani and stapedius reflex**

Loud sound elicits reflex contraction of tensor tympani and stapedius, which attenuates movement of the tympanic membrane and middle ear ossicles (see Ch. 36). Afferent impulses travel in the cochlear nerve to the cochlear nuclei in the brain stem. Efferent fibres to tensor tympani arise in the trigeminal motor nucleus and travel in the mandibular division of the trigeminal nerve. Efferent fibres to stapedius originate in the facial nucleus and travel in the facial nerve.

**Salivatory nucleus**

The salivatory (salivary) nucleus is near the upper pole of the vagal nucleus, just above the pontomedullary junction and near the inferior pole of the facial nucleus. It is customarily divided into superior and inferior salivatory nuclei, which send preganglionic parasympathetic fibres into the facial and glossopharyngeal nerves for the control of the salivary and lacrimal glands.
MIDBRAIN

EXTERNAL FEATURES AND RELATIONS

The midbrain traverses the hiatus in the tentorium cerebelli, and connects the pons and cerebellum with the forebrain. It is the shortest brain stem segment, not more than 2 cm in length, and most of it lies in the posterior cranial fossa. Lateral to it are the parahippocampal gyri, which hide its sides when the inferior surface of the brain is examined. For descriptive purposes, the midbrain may be divided into a dorsal tectum and right and left cerebral peduncles, each of which is further divided into a ventral crus cerebri and a dorsal tegmentum by a pigmented lamina, the substantia nigra. The two crura are separate, whereas the tegmental parts are united and traversed by the cerebral aqueduct that connects the third and fourth ventricles. The tectum lies dorsal to the cerebral aqueduct, and consists of the pretectal area and the paired superior and inferior colliculi (corpora quadrigemina).

The crura cerebri are superficially corrugated and emerge from the cerebral hemispheres. They converge as they descend and meet as they enter the pons, where they form the caudolateral boundaries of the interpeduncular fossa (Fig. 19.18, Fig. 19.19). At the level of the tentorial incisure, the basilar artery divides in the interpeduncular fossa into the right and left posterior cerebral arteries. The superior cerebellar arteries branch from the basilar artery immediately before this bifurcation. The posterior cerebral and superior cerebellar arteries both run laterally around the ventral surface of the crus, the former passing above the tentorium cerebelli, the latter passing below. The oculomotor and trochlear nerves lie between the two arteries. The roots of the oculomotor nerve emerge from the medial aspect of the crus (Fig. 15.7).

The posterior communicating artery joins the posterior cerebral artery on the medial surface of the peduncle in the interpeduncular fossa. The median caudal part of the interpeduncular fossa constitutes the posterior perforated substance, which is pierced by central (perforating) branches of the posterior cerebral arteries. The optic tract winds dorsolaterally around the crus near where the latter emerges from the cerebral hemispheres.
The superior and inferior colliculi are two paired eminences on the dorsal surface of the midbrain (Fig. 19.3). They lie rostral to the superior medullary velum, inferior to the pineal gland and caudal to the posterior commissure. Below the splenium of the corpus callosum, they are partly overlain by the pulvinar of the thalamus. The superior and inferior colliculi are separated by a cruciform sulcus. The upper limit of the sulcus expands into a depression for the pineal gland, and a median frenulum veli is prolonged from its caudal end down over the superior medullary velum. The trochlear nerves emerge lateral to the frenulum, pass ventrally over the lateral aspects of the cerebral peduncles and traverse the interpeduncular cistern to the petrosal end of the
cavernous sinus. The superior colliculi, larger than the inferior, are centres for visual reflex responses. The inferior colliculi are a part of the ascending auditory pathway.

A brachium passes ventrolaterally from the lateral aspect of each colliculus (Fig. 19.3). The brachium of the superior colliculus (superior quadrigeminal brachium) passes below the pulvinar, partly overlapping the medial geniculate body, and conveys fibres from the retina to the superior colliculus. The brachium of the inferior colliculus (inferior quadrigeminal brachium) ascends ventrally and conveys fibres from the lateral lemniscus and inferior colliculus to the medial geniculate body.
INTERNAL STRUCTURE

Transverse sections of the midbrain

In transverse section, the cerebral peduncles are seen to be composed of dorsal and ventral regions separated by the substantia nigra (Fig. 19.18, Fig. 19.19). On each side, the dorsal region is the tegmentum and the ventral part is the crus cerebri. The tegmenti are continuous across the midline but the crura are separated.

Crus cerebri

The crus cerebri is approximately semilunar in section, being convex externally and concave internally. It contains corticobulbar and corticospinal fibres. Corticobulbar fibres terminate at various brainstem levels, some in association with the cranial nerve nuclei (corticonuclear fibres). Corticospinal fibres pass uninterrupted through the brainstem to enter the medullary pyramid and, thereafter, form the corticospinal tracts of the spinal cord (Fig. 18.18). Corticonuclear and corticospinal fibres occupy the middle two-thirds of the crus cerebri. Corticopontine fibres arise in the cerebral cortex and form two groups, both of which end in the pontine nuclei. Frontopontine fibres from the frontal lobe, principally areas 6 and 4, traverse the internal capsule and then occupy the medial sixth of the ipsilateral crus cerebri. Temporopontine fibres, which originate largely from the posterior region of the temporal lobe, traverse the internal capsule and then run in the lateral sixth of the ipsilateral crus. Parietopontine and occipitopontine fibres are also described in the crus, lying medial to the temporopontine fibres. There are few fibres from the primary sensory cortex in corticopontine projections.

Mesencephalic tegmentum

The mesencephalic tegmentum is continuous with the pontine tegmentum. At inferior collicular levels, grey matter is restricted to scattered collections of neurones in the reticular formation and a central, periaqueductal region ventral to the cerebral aqueduct. The trochlear nucleus lies in the latter region, near the midline, in a position corresponding to the abducens and hypoglossal nuclei at more caudal levels. It extends through the lower half of the midbrain, just caudal to the oculomotor nucleus and immediately dorsal to the medial longitudinal fasciculus.

The mesencephalic nucleus of the trigeminal nerve occupies a lateral position in the central grey matter (see Fig. 19.2). It ascends from the main trigeminal sensory nucleus in the pons to the level of the superior colliculus in the midbrain. Its large ovoid neurones are unipolar, like those in peripheral sensory ganglia. They are arranged in many small groups which extend as curved laminae on the lateral margins of the periaqueductal grey matter:
neurones are most numerous caudally.

Apart from these nuclei, the mesencephalic tegmentum contains many other scattered neurones, most of which are included in the reticular formation.

The white matter of the mesencephalic tegmentum contains the majority of the tracts present in the pontine tegmentum. The decussation of the superior cerebellar peduncles is particularly prominent. Numerous ascending fibres enter the mesencephalic tegmentum from the cerebellum and pass ventromedially, decussating in the midline (Fig. 19.18). Thereafter, ascending fibres encapsulate and penetrate the red nucleus, in which some fibres, or their collaterals, terminate (Fig. 19.19). However, the majority of fibres ascend to terminate in the nucleus ventralis lateralis of the thalamus. A relatively small number of uncrossed fibres are believed to end in the periaqueductal grey matter and reticular formation, the interstitial nucleus and the nucleus of the posterior commissure (nucleus of Darkschewitsch). The latter nucleus may send efferent fibres to the medial longitudinal fasciculus and posterior commissure. Descending fascicles from the superior cerebellar peduncles also apparently end in the pontine and medullary reticular formation, the olivary complex and, possibly, motor cranial nerve nuclei.

The medial longitudinal fasciculus adjoins the somatic efferent cell column, dorsal to the decussating superior cerebellar peduncles (Fig. 19.18). The medial, trigeminal, lateral and spinal lemnisci form a curved band dorsolateral to the substantia nigra. Fibres in the medial, trigeminal and spinal lemnisci continue a rostral course to synapse with neurones in the lateral and medial parts of the ventral posterior nucleus of the thalamus. Some fibres of the lateral lemniscus end in the nucleus of the inferior colliculus, or send collaterals to it. The remaining lateral lemniscal fibres join with fibres originating in the inferior colliculus and enter the inferior quadrigeminal brachium, which carries them to the medial geniculate body.

At the level of the superior colliculus, the tegmentum contains the red nucleus (Fig. 19.19), which extends rostrally into the subthalamic region. The ventromedial central grey matter around the aqueduct contains the elongated oculomotor nucleus, which is adjacent ventrolaterally to the medial longitudinal fasciculus, and caudally reaches the trochlear nucleus. The oculomotor nucleus is divisible into neuronal groups which may be partially correlated with the motor distribution of the oculomotor nerve. A group of preganglionic parasympathetic neurones which control the activity of smooth muscle within the eyeball, the Edinger–Westphal nucleus, lies dorsal to the oculomotor nucleus.

**Substantia nigra**

The substantia nigra is a large nucleus that extends through the whole length
of the midbrain (Fig. 19.18, Fig. 19.19). It has major connections with the basal ganglia and is central to the pathology of Parkinson's disease (Ch. 22).

The substantia nigra is located between the crus cerebri ventrolaterally and ascending lemniscal fibres dorsomedially. Its medial part is traversed by oculomotor axons passing ventrally to their point of exit in the interpeduncular fossa. The substantia nigra is divided into a dorsal pars compacta and a ventral pars reticulata; the neurones in each part have quite different connections.

The pars compacta consists of darkly pigmented neurones, which contain neuromelanin granules. Their arrangement is irregular and they partially penetrate the subjacent pars reticulata. Pigmentation increases with age, is most abundant in primates, maximal in man, and present even in albinos. The pigmented pars compacta neurones synthesize dopamine as their neurotransmitter and project predominantly to the corpus striatum of the basal ganglia as well as to other sites. The pars compacta corresponds to the dopaminergic cell group A9 (Fig. 22.10). Two other dopaminergic cell groups are found in the ventral tegmentum: cell group A10 in the rostromedial region, which corresponds to the ventral tegmental area (of Tsai), and cell group A8 in the dorsolateral reticular area, which forms the nucleus parabrachialis pigmentosus. The whole ventral tegmental system of dopaminergic neurones appears to act as an integrative centre for adaptive behaviour. It projects via a number of pathways, mainly through ascending fibres in the ipsilateral medial forebrain bundle. These pathways are a mesodiencephalic system, which terminates in thalamic and hypothalamic nuclei; a mesostriatal projection to the caudate nucleus and putamen; a mesolimbic pathway to the nucleus accumbens, olfactory tubercle, lateral septum, interstitial nucleus of the stria terminalis, amygdala and entorhinal cortex; and mesocortical fibres that project to most cortical areas, particularly the prefrontal, orbitofrontal and cingulate cortex.

The pars compacta projects heavily to the caudate nucleus and putamen in a topographically organized fashion (nigrostriatal fibres). Lesser projections end in the globus pallidus and subthalamic nucleus. In Parkinson's disease, the levels of dopamine in the substantia nigra and striatum decrease dramatically as a result of the degeneration of pars compacta neurones (Ch. 22).

The pars reticulata of the substantia nigra extends rostrally as far as the subthalamic region. It is considered to be a homologue of the medial (internal) segment of the globus pallidus, which it resembles in terms of cell type and connectivity. It consists of clusters of neurones, many of which intermingle with fibres of the crus cerebri. Most pars reticulata neurones are GABAergic and also contain high levels of iron.
There are reciprocal connections between the substantia nigra and the basal ganglia. Efferent fibres from the basal ganglia terminate largely, but not exclusively, in the pars reticulata. Topographically organized striatonigral fibres originate from the caudate nucleus and putamen and project to the pars reticulata. The head of the caudate nucleus projects to the rostral third of the substantia nigra, while the putamen projects to all parts. The fibres end in axodendritic synapses. A small number of GABAergic pallidonigral fibres from the lateral (external) segment of the globus pallidus end mostly in the pars reticulata. The subthalamic nucleus sends an important glutamatergic projection to the pars reticulata and to the globus pallidus. Subthalamonigral and subthalamopallidal projections are important in the pathophysiology of movement disorders such as Parkinson's disease and dyskinesias (Ch. 22).

GABAergic neurones in the pars reticulata project rostrally to the ventral anterior and dorsomedial thalamic nuclei, and caudally to the pedunculopontine nucleus and reticular formation, whence impulses are relayed to spinal ventral horn neurones. A pars lateralis of the substantia nigra is recognizable, but small, in man. It projects to the ipsilateral superior colliculus, and may be involved in the control of saccadic eye movements.

Some corticonigral fibres appear to exist, passing from precentral and postcentral gyri to neurones in the pars reticulata.

**Red nucleus**

The red nucleus is a pink, ovoid mass, approximately 5 mm in diameter and lying dorsomedial to the substantia nigra (Fig. 19.19). The tint appears only in fresh material and is caused by a ferric iron pigment in its multipolar neurones. The latter are of varying size and their relative proportions and arrangement vary between species. In primates the magnocellular element is decreased, and there is a reciprocal increase in the size of the parvocellular component. Small multipolar neurones occur in all parts of the nucleus. In man, the larger neurones are restricted to the caudal part of the nucleus and have been estimated to be as few as 200 in number. The magnocellular element is considered phylogenetically old, which accords with the parvocellular predominance in primates. Rostrally, the red nucleus is poorly demarcated, and it blends into the reticular formation and caudal pole of the interstitial nucleus. It is traversed and surrounded by fascicles of nerve fibres, including many from the oculomotor nucleus.

The principal afferent connections of the red nucleus are corticorubral and cerebellorubral fibres. Uncrossed corticorubral fibres originate from primary somatomotor and somatosensory areas. In animals, the red nucleus receives fibres from the contralateral nucleus interpositus (which corresponds to the human globose and emboliform nuclei), and dentate nucleus, via the superior cerebellar peduncle. It has bilateral, probably reciprocal, connections with the
superior colliculi. In humans, the rubrospinal tract is small and originates from the caudal magnocellular part of the red nucleus. Few fibres reach the cervical cord. The fibres decussate and then run obliquely laterally in the ventral tegmental decussation, ventral to the tectospinal decussation, and dorsal to the medial lemniscus. On reaching the grey matter ventral to the inferior cerebellar peduncle, the tract turns caudally to enter the lateral part of the lateral lemniscus. It continues descending ventral to the tract and nucleus of the trigeminal nerve throughout the medulla, and enters the upper part of the cervical cord intermingled with fibres of the lateral corticospinal tract. Some efferent axons form a rubrobulbar tract to motor nuclei of the trigeminal, facial, oculomotor, trochlear and abducens nerves.

The largest group of efferents from the red nucleus in man is a descending component of the ipsilateral, central tegmental tract. Initially, this tract lies lateral to the medial longitudinal fasciculus and dorsolateral to both the red nucleus and the decussation of the superior cerebellar peduncles (Fig. 19.9, Fig. 19.10, Fig. 19.11, Fig. 19.18). Most fibres arise from the parvocellular part of the red nucleus and pass to the ipsilateral inferior olivary nucleus in the medulla. Some tract fibres terminate in the brain stem reticular nuclei. Ascending and descending axons from the brain stem reticular formation also run in the central tegmental tract. These axons include dorsal and ventral ascending noradrenergic bundles, a ventral ascending serotoninergic bundle, and some fibres of dorsal and ventral ascending cholinergic bundles.

As mentioned elsewhere (p. 269), lesions of the corticospinal system in man result in permanent paresis or paralysis. In monkeys, although initially complete, the paralysis disappears and good recovery ensues. The explanation for this interprimate variability in recovery from corticospinal lesions appears to lie in the differential capacity of the rubrospinal system to compensate for loss of corticospinal drive. Monkeys never fully recover from combined lesions of both the corticospinal and rubrospinal tracts, which suggests that the two systems are functionally interrelated in the control of movement. Both encode force, velocity and direction parameters, but the rubrospinal system primarily directs activity both during the terminal phase of a movement and preceding a movement. There is, thus, overlap of activity in the two systems for all parameters during movements of limbs and even of individual digits. The corticospinal system is most active during the learning of new movements, whereas the rubrospinal system is most active during the execution of learnt automated movements.

The rubro-olivary projection, which travels in the central tegmental tract, connects the red nucleus indirectly to the contralateral cerebellar cortex. The cerebellum is thought to play a role in motor learning, and so the rubro-olivary system could switch the control of movements from the corticospinal to the rubrospinal system for programmed automation. The relative absence of a rubrospinal system in man could explain the poor recovery of motor
function after stroke.

**Oculomotor nucleus**

The nuclear complex from which the efferent fibres of the oculomotor nerve arise consists of several groups of large motor neurones (collectively, the oculomotor nucleus; Fig. 19.19) and smaller preganglionic parasympathetic neurones (the Edinger–Westphal nucleus). The motor neurone groups of the oculomotor nucleus innervate, in dorsoventral order, the ipsilateral inferior rectus, inferior oblique and medial rectus. A medially placed column of cells innervates the contralateral superior rectus: the axons from this subnucleus decussate in its caudal part. The medial rectus subnucleus consists of three anatomically distinct subpopulations. The ventral portion, which contains the largest number of motor neurones, occupies the rostral two-thirds; a subpopulation of smaller motor neurones lies dorsally throughout the rostral two-thirds of the nucleus and innervates the small orbital fibres of the medial rectus; and another subpopulation lies dorsolaterally in the caudal two-thirds of the nucleus.

A median subnucleus of large neurones, the caudal central nucleus, lies at the caudal pole of the oculomotor nucleus adjacent to the superior rectus and medial rectus subnuclei. In non-human primates, approximately 30% of the motor neurones in this subnucleus innervate levator palpebrae superioris bilaterally, which is unique for paired skeletal muscles.

The Edinger–Westphal nucleus, composed of small, multipolar, preganglionic parasympathetic neurones, lies dorsal to the main oculomotor nucleus. Its neurones give rise to axons that travel in the oculomotor nerve and synapse with postganglionic neurones in the ciliary ganglion.

Fascicles of axons from all of these subnuclei course forward in the midbrain and emerge as the oculomotor nerve in the interpeduncular fossa. The fascicles are most probably arranged from medial to lateral subserving the pupil, inferior rectus, medial rectus, levator palpebrae superioris and superior rectus, and inferior oblique. The human oculomotor nerve contains approximately 15,000 axons.

Afferent inputs to the oculomotor nuclear complex include fibres from the rostral interstitial nucleus of the medial longitudinal fasciculus and the interstitial nucleus of Cajal, both of which are involved in the control of vertical and torsional gaze. Other inputs come, either directly or indirectly, from the nuclei of the posterior commissure, the interstitial nucleus of Cajal, the frontal eye fields, the superior colliculus, the dentate nucleus and other cortical areas. The medial longitudinal fasciculus carries connections from the trochlear, abducens and vestibular nuclei; the medial and lateral vestibular nuclei project to the medial rectus subnucleus.
Afferent inputs to the Edinger–Westphal nucleus come primarily from the pretectal nuclei bilaterally, mediating the pupillary light reflex and from the visual cortex, mediating accommodation.

**Trochlear nucleus**

The trochlear nucleus lies in the grey matter in the floor of the cerebral aqueduct, level with the upper part of the inferior colliculus (Fig. 19.1, Fig. 19.18). It is in line with the ventromedial part of the oculomotor nucleus, in the position of the somatic efferent column. The medial longitudinal fasciculus is ventral and lateral to it. The oculomotor and trochlear nuclei often overlap slightly but can be distinguished by the smaller size of the trochlear neurones. The afferent inputs to the trochlear nucleus are similar to those described for the oculomotor nucleus. Trochlear efferent fibres pass laterodorsally round the central grey matter, then descend medial to the trigeminal mesencephalic nucleus to reach the upper end of the superior medullary velum, where they decussate and emerge lateral to the frenulum. A few fibres remain ipsilateral.

**Medial longitudinal fasciculus**

The medial longitudinal fasciculus (Fig. 19.9, Fig. 19.18, Fig. 39.12) is a heavily myelinated composite tract, lying near the midline, ventral to the periaqueductal grey matter. It ascends to the interstitial nucleus of Cajal, which lies in the lateral wall of the third ventricle, just above the cerebral aqueduct. The fasciculus retains its position relative to the central grey matter through the midbrain, pons and upper medulla, but is displaced ventrally by successive decussations of the medial lemnisci and lateral corticospinal tracts. At spinal levels it is synonymous with the medial vestibulospinal tract.

The medial longitudinal fasciculus interconnects the oculomotor, trochlear, abducens, Edinger–Westphal, vestibular, reticular and spinal accessory nuclei, coordinating conjugate eye movements and associated movements of the head and neck. Lesions cause internuclear ophthalmoplegia. All four vestibular nuclei contribute ascending fibres. Those from the superior nucleus remain uncrossed, while the others are partly crossed. Some fibres reach the interstitial and posterior commissural nuclei, and some decussate to the contralateral nuclei. Descending axons, from the medial vestibular nuclei and perhaps the lateral and inferior nuclei, partially decussate and descend in the fasciculus to form the medial vestibulospinal tract (Fig. 18.19). Fibres join the fasciculus from the dorsal trapezoid, lateral lemniscal and posterior commissural nuclei, which means that both the cochlear and vestibular components of the vestibulocochlear nerve may influence movements of the eyes and head via the medial longitudinal fasciculus. Some vestibular fibres may ascend in the medial longitudinal fasciculus as far as the thalamus.
The inferior colliculus (Fig. 19.18) is part of the ascending auditory pathway (Ch. 37) and is the principal site of termination of the lateral lemniscus. It has a central, ovoid, main nucleus, which is continuous with the periaqueductal grey matter. It is surrounded by a lamina of nerve fibres, many from the lateral lemniscus, which terminate in it. The central nucleus has dorsomedial and ventrolateral zones, which are covered by a dorsal cortex. In humans, the cortex has four cytoarchitectonic layers: layer I contains small neurones with flattened radial dendritic fields; layer II, medium-sized neurones with ovoid dendritic fields aligned parallel with the collicular surface; layer III, medium-sized neurones with spherical dendritic fields; and layer IV, large neurones with variably shaped dendritic fields. The central nucleus is laminated. Bands of cells with disc-shaped or stellate dendritic fields orthogonally span the fibre layers in which the terminals of lateral lemniscal fibres ramify. The neurones are sharply tuned to frequency, and the laminae may represent the structural basis of tonal discrimination. Experimental studies have found cells driven by low frequencies in the dorsal laminae, and others driven by high frequencies in the ventral laminae. Neurones are broadly frequency-tuned in the dorsal cortex and lateral nucleus.

Most efferent fibres from the inferior colliculus travel via the inferior brachium to the ipsilateral medial geniculate body. Lemniscal fibres relay only in the central nucleus, and some pass without relay to the medial geniculate body. In man, the ventral division of the medial geniculate body receives a topographic projection from the central nucleus and the dorsal division receives a similar projection from the dorsal cortex. Some colliculogeniculate fibres do not relay in the geniculate body, but continue, with those that do, via the auditory radiation to the auditory cortex. A descending projection from the auditory cortex reaches the inferior colliculus via the medial geniculate body. Some fibres may traverse this projection without relay. This descending path may produce effects at levels from the medial geniculate body downwards, and it probably links with efferent cochlear fibres, through the superior olivary and cochlear nuclei.

Inferior collicular projections to the brain stem and spinal cord appear to traverse the superior colliculi before they descend. In this way they connect with the origins of the tectospinal and tectotegmental tracts. These projections are relatively small and probably mediate reflex turning of the head and eyes in response to sounds.

In experimental animals, lesions of either the inferior colliculus or its brachium produce defects in tonal discrimination, sound localization and auditory reflexes. The effects of such lesions are poorly documented in man.
Superior colliculus

The superior colliculus is a laminated structure. At successive depths from the external surface, it may be divided into a stratum zonale, cinereum, opticum and lemnisci. The stratum lemnisci may be subdivided into the stratum griseum medium, album medium, griseum profundum and album profundum. These seven layers have also been termed zonal, superficial grey, optic, intermediate grey, deep grey, deep white and periventricular strata. The two schemes do not completely accord, but, as a generalization, layers may be considered to be composed alternately of neuronal somata or their processes. The zonal layer consists chiefly of myelinated and non-myelinated fibres from the occipital cortex (areas 17, 18 and 19), which arrive as the external corticotectal tract. It also contains a few small neurones, which are horizontally arrayed. The superficial grey layer (stratum cinereum) forms a crescentic lamina over the deeper layers and contains many small multipolar interneurones, on which cortical fibres synapse. The optic layer consists partly of fibres from the optic tract. As they terminate, they permeate the entire anterior–posterior extent of the superficial layers with numerous collateral branches. This arrangement provides a retinotopic map of the contralateral visual field, in which the fovea is represented anterolaterally. Retinal axons terminate in clusters from specific retinotectal neurones and as collaterals of retinogeniculate fibres. The layer also contains some large multipolar neurones. Efferent fibres to the retina are said to start in this layer.

The intermediate grey and white layers collectively constitute the main receptive zone. The main afferent input is the medial corticotectal path from layer V neurones of the ipsilateral occipital cortex (area 18), and from other neocortical areas that are concerned with ocular following movements. Afferent fibres are also received from the contralateral spinal cord (via spinotectal and spinothalamic routes), the inferior colliculus, and the locus coeruleus and raphe nuclei (from noradrenergic and serotonergic neurones). The deep grey and deep white layers adjacent to the periaqueductal grey matter are collectively called the parabigeminal nucleus. They contain neurones whose dendrites extend into the optic layer, and whose axons of which form many of the collicular efferents.

The superior colliculus receives afferents from many sources including the retina, spinal cord, inferior colliculus and occipital and temporal cortices. The first three of these pathways convey visual, tactile and probably thermal, pain and auditory impulses. Collicular efferents pass to the retina, lateral geniculate nucleus, pretectum, parabigeminal nucleus, the inferior, medial and lateral pulvinar, and to numerous sites in the brain stem and spinal cord. Fibres passing from the pulvinar are relayed to primary and secondary visual cortices and form an extrageniculate retinocortical pathway for visual orientation and attention.
The tectospinal and tectobulbar tracts start from neurones in the superior colliculi. They sweep ventrally round the central grey matter to decussate ventral to the oculomotor nuclei and medial longitudinal fasciculi as part of the dorsal tegmental decussation. The tectospinal tract descends ventral to the medial longitudinal fasciculus as far as the medial lemniscal decussation in the medulla, where it diverges ventrolaterally to reach the spinal ventral white column near the ventral lip of the ventral median fissure. Tectospinal fibres descend to cervical segments. The tectobulbar tract, mainly crossed, descends near the tectospinal tract, and ends in the pontine nuclei and motor nuclei of the cranial nerves, particularly those innervating the oculogyrpic muscles. It subserves reflex ocular movements. Other tectotegmental fibres reach various tegmental reticular nuclei in the ipsilateral mesencephalic and contralateral pontomedullary reticular formation (gigantocellular reticular, caudal pontine reticular, oral pontine reticular nuclei), and the substantia nigra and red nucleus. Tectopontine fibres, which probably descend with the tectospinal tract, terminate in dorsolateral pontine nuclei, with a relay to the cerebellum. A tecto-olivary projection, from deeper collicular laminae to the upper third of the medial accessory olivary nucleus, exists in primates. It is crossed and links with the posterior vermis.

In animals, central collicular stimulation produces contralateral head movement as well as movements involving the eyes, trunk and limbs, which implicates the superior colliculus in the integration of vision and body movement.

**Pretectal nucleus**

The pretectal nucleus is a poorly defined mass of neurones at the junction of the mesencephalon and diencephalon. It extends from a position dorsolateral to the posterior commissure caudally towards the superior colliculus, with which it is partly continuous. It receives fibres from the visual cortex via the superior quadrigeminal brachium, from the retina via the lateral root of the optic tract, and from the superior colliculus. Its efferent fibres reach both parasympathetic Edinger–Westphal nuclei. Those which decussate pass ventral to the aqueduct or through the posterior commissure. In this way, sphincter pupillae contract in both eyes in response to impulses from either eye. This bilateral light reflex may not be the sole activity of the pretectal nucleus. Some of its efferents project to the pulvinar and deep laminae of the superior colliculus, and provide another extrageniculate path to the cerebral cortex.
BRAIN STEM RETICULAR FORMATION

The brain stem contains extensive fields of intermingled neuronal cell bodies and nerve fibres, which are collectively termed the reticular formation. The reticular regions are often regarded as phylogenetically ancient, representing a primitive nerve network upon which more anatomically organized, functionally selective, connections have developed during evolution.

Reticular regions tend to be ill-defined collections of neurones with diffuse connections. Their conduction paths are difficult to define, often complex and polysynaptic, and they have ascending and descending components that are partly crossed and uncrossed. Their components subserve somatic and visceral functions. They also include some distinct and important cell groups, which are distinguished on the basis of their neurotransmitter substances. These include dopaminergic and noradrenergic neurones (group A), serotonergic (group B) adrenergic (group C) and cholinergic (group Ch) neurones.

Studies with the Golgi technique show that few brain stem reticular neurones are classic Golgi type II neurones (i.e. with short axons that branch locally). In contrast, they have long dendrites that spread across the long axis of the brain stem in transverse sheets. These radiating dendrites may spread into 50% of the cross-sectional area of their half of the brain stem, and they are intersected by, and may synapse with, a complex of ascending and descending fibres. Many axons of reticular neurones ascend or descend, or bifurcate to do both. They often travel far, perhaps through the whole brain stem and even beyond. As an example, a bifurcating axon from a cell in the magnocellular medullary nucleus may project rostrally into the upper medulla, pons, midbrain tegmentum, subthalamus, hypothalamus, dorsal thalamus, septum, limbic system and neocortex, while its descending branch innervates the reticular core of the lower medulla and may reach the cervical spinal intermediate grey matter (laminae V and VI). Many reticular neurones have unidirectional, shorter axons which synapse with the radiating dendrites of numerous other neurones en route, and give off collaterals which synapse with cells in ‘specific’ brain stem nuclei or cortical formations, such as the cerebellum. Multitudes of afferent fibres converging on individual neurones, and the myriad destinations of efferent fibres, provide the structural basis for considering the reticular formation to be ‘polymodal’, ‘diffuse’ or ‘non-specific’ in function.

A contrasting dendritic form is also found, in which dendrites are short, sinuous or curved, branch profusely and pursue re-entrant courses at the perimeter of a nuclear group, defining a boundary between it and its environs. Neurones with an intermediate dendritic complexity occur in and near such nuclei and vary in density in much of the remaining reticular formation. In different zones, the proportion of different sizes of neuronal somata varies. Some regions contain only small to intermediate multipolar cells (‘parvocellular’ regions). However, there are a few areas where these mingle with large multipolar neurones in ‘gigantocellular’ or ‘magnocellular’ nuclei.

In general terms, the reticular formation is a continuous core that traverses the whole brain stem, and is continuous below with the reticular intermediate spinal grey laminae. It is divisible, on the basis of cytoarchitectonic, chemoarchitectonic and functional criteria, into three bilateral longitudinal columns: median; medial, containing mostly large reticular neurones; and lateral, containing mostly small to intermediate
neurones (Fig. 19.20).

**Fig. 19.20** Dorsal aspect of the brain stem showing the approximate location of nuclei of the reticular formation. Nuclei of the median and paramedian nuclear column: magenta; medial column nuclei: purple, lateral column nuclei: blue.

**MEDIAN COLUMN OF RETICULAR NUCLEI**

The median column of reticular nuclei extends throughout the medulla, pons and midbrain and contains neurones that are largely aggregated in bilateral, vertical sheets, blended in the midline and occupying the paramedian zones. Collectively they are called the nuclei of the raphe, or raphe nuclei. Many neurones in raphe nuclei are serotoninergic and are grouped into nine clusters, B1–9. The raphe pallidus nucleus and associated raphe obscurus nucleus lie in the upper two-thirds of the medulla and cross the pontomedullary junction. The raphe magnus nucleus, corresponding to many B3 neurones, partly overlaps them, and ascends into the pons. Above it is the pontine raphe nucleus, which is formed by the cell group B5. Also located in the pons is the central superior raphe nucleus, which contains parts of cell groups B6 and B8. The dorsal (rostral) raphe nucleus, approximating to cell group B7, extends through much of the midbrain.

Axons originating from the serotoninergic raphe neurones ramify extensively throughout the CNS. Although many of these fibres are diffusely distributed, others have more specific connections. For example, whereas the central superior raphe nucleus projects divergently to all areas of the cerebral cortex, different neurones in
the dorsal raphe nucleus not only project specifically to circumscribed regions of the frontal, parietal and occipital cortices, but also to functionally related regions of the cerebellar cortex. Similarly, the caudate nucleus and putamen receive a preferential input from the dorsal raphe nucleus, whereas the hippocampus, septum and hypothalamus are innervated mainly by cells in the central superior mesencephalic raphe nucleus.

All raphe nuclei provide mainly serotonergic descending projections, which terminate in the brain stem and spinal cord. Brain stem connections are multiple and complex. For example, the dorsal raphe nucleus, in addition to sending a large number of fibres to the locus coeruleus, projects to the dorsal tegmental nucleus and most of the rhombencephalic reticular formation, together with the central superior, pontine raphe and raphe magnus nuclei.

Raphe spinal serotonergic axons originate mainly from neurones in the raphe magnus, pallidus and obscurus nuclei. They project as ventral, dorsal and intermediate spinal tracts in the ventral and lateral funiculi, and terminate respectively in the ventral horns and laminae I, II and V of the dorsal horns of all segments, and in the thoracolumbar intermediolateral sympathetic and sacral parasympathetic preganglionic cell columns. The dorsal raphe spinal projections function as a pain control pathway that descends from a mesencephalic pain control centre located in the periaqueductal grey matter, dorsal raphe and cuneiform nuclei (Ch. 18). The intermediate raphe-spinal projection is inhibitory, and, in part, modulates central sympathetic control of cardiovascular function. The ventral raphe spinal system excites ventral horn cells and could function to enhance motor responses to nociceptive stimuli.

Principally, the mesencephalic serotonergic raphe system is reciprocally interconnected rostrally with the limbic system, septum, prefrontal cortex and hypothalamus. Efferents ascend and form a large ventral and a diminutive dorsal pathway. Both originate from neurones in the dorsal and central superior raphe nuclei. The raphe magnus nucleus also contributes to the dorsal ascending serotonergic pathway, which is at first incorporated into the dorsal longitudinal fasciculus (of Schütz). A few fibres terminate in the central mesencephalic grey matter and posterior hypothalamus, but most continue into the medial forebrain bundle and merge with the axons of the ventral pathway, which are distributed to the same targets. The fibres of the ventral ascending serotonergic pathway exit the ventral aspect of the mesencephalic raphe nuclei, and then course rostrally through the ventral tegmentum from where fibres pass to the ventral tegmental area, substantia nigra and interpeduncular nucleus. A large number of fibres then enter the habenulointerpeduncular tract and run rostrally to innervate the habenular nucleus, intralaminar, midline, anterior, ventral and lateral dorsal thalamic nuclei, and the lateral geniculate body. The ventral ascending serotonergic pathway enters the medial forebrain bundle in the lateral hypothalamic area and splits to pass medially and laterally. The fibres in the medial tract terminate in the mammillary body, dorsomedial, ventromedial, infundibular, anterior and lateral hypothalamic, medial and lateral preoptic and suprachiasmatic nuclei. Those in the lateral tract take the ansa peduncularis–ventral amygdalofugal path to the amygdala, striatum and caudal neocortex. The medial forebrain bundle carries the remaining ventral ascending serotonergic axons into the medullary stria, stria terminalis, fornix, diagonal band, external capsule, cingulate fasciculus and medial olfactory stria, to terminate in all the
structures that these systems interconnect.

Major afferents into the mesencephalic raphe nuclei include those from the interpeduncular nucleus, linking the limbic and serotoninergic systems; from the lateral habenular nucleus, linking the septum, preoptic hypothalamus and prefrontal cortex via the habenulointerpeduncular tract and the medial forebrain bundle; and from the pontine central grey matter.

The ascending raphe system probably functions to moderate forebrain activities, particularly limbic, septal and hypothalamic activities. A degree of region-specific connectivity suggest that it exerts precise, as well as tonal, control.
The medial column of reticular nuclei is composed predominantly of neurones of medium size, although very large neurones are found in some regions, and most have processes orientated in the transverse plane. In the lower medulla the column is indistinct, and is perhaps represented by a thin lamina lateral to the raphe nuclei. However, in the upper medulla it expands into the medullary gigantocellular (magnocellular) nucleus, which lies ventrolateral to the hypoglossal nucleus, ventral to the vagal nuclei and dorsal to the inferior olivary complex. Ascending further, the column continues as the pontine gigantocellular (magnocellular) nucleus, which lies medially in the tegmentum. Its neurones suddenly diminish in size to form, in rostral order, the almost coextensive caudal and oral pontine tegmental reticular nuclei. It then expands into the cuneiform nucleus and subcuneiform nucleus, before fading away in the midbrain tegmentum.

Axons of medial reticular column neurones form a multisynaptic ascending and descending system within the column, and ultimately enter the spinal cord and diencephalon. Descending fibres form the pontospinal (lateral reticulospinal), and bulbospinal (medial reticulospinal) tracts. Pontospinal axons arise from neurones in the caudal and oral parts of the pontine reticular nucleus, descend uncrossed in the ventral spinal funiculus, and terminate in spinal cord laminae VII, VIII and IX. Bulbospinal axons descend bilaterally to end in laminae VII, VIII, IX, and X, and ipsilaterally to end in laminae IV, V and VI. The system modulates spinal motor function and segmental nociceptive input.

Afferent components to the medial reticular nuclear column include the spinoreticular projection and collaterals of centrally projecting spinal trigeminal, vestibular and cochlear fibres. Spinoreticular fibres arise from neurones in the intermediate grey matter of the spinal cord. They decussate in the ventral white commissure, ascend in the ventrolateral funiculus, usually via several neurones, and terminate not only at all levels of the medial column of reticular nuclei but also in the intralaminar nuclei of the thalamus. Three areas of the medial reticular zone receive particularly high densities of terminations. These are the combined caudal and rostral ends of the gigantocellular and central nuclei, respectively, and the caudal pontine reticular nucleus and the pontine tegmentum. Retinorecital and tectoreticular fibres relay visual information and the medial forebrain bundle transmits olfactory impulses.

Efferents from the medial column of reticular nuclei project through a multisynaptic pathway within the column to the thalamus. Areas of maximal termination of spinoreticular fibres also project directly to the intralaminar thalamic nuclei. The multisynaptic pathway is integrated into the lateral column of reticular nuclei with cholinergic neurones in the lateral pontine
tegmentum. The intralaminar thalamic nuclei project directly to the striatum and neocortex.
LATERAL COLUMN OF RETICULAR NUCLEI

The lateral column of reticular nuclei contains six nuclear groups. These are the parvocellular reticular area, superficial ventrolateral reticular area, lateral pontine tegmental noradrenergic cell groups A1, A2, A4–A7 (A3 is absent in primates), adrenergic cell groups C1–C2 and cholinergic cell groups Ch5–Ch6. The column descends through the lower two-thirds of the lateral pontine tegmentum and upper medulla, where it lies between the gigantocellular nucleus medially, and the sensory trigeminal nuclei laterally. It continues caudally and expands to form most of the reticular formation lateral to the raphe nuclei. It abuts the superficial ventrolateral reticular area, nucleus solitarius, nucleus ambiguus and vagal nucleus, and there contains the adrenergic cell group C2, and the noradrenergic group A2.

The lateral paragigantocellular nucleus lies at the rostral pole of the diffuse superficial ventrolateral reticular area (at the level of the facial nucleus). The zone extends caudally as the nucleus retroambiguus and descends into the spinal cord. It contains noradrenergic cell groups A1, A2, A4 and A5, and the adrenergic cell group C1. The ventrolateral reticular area is involved in cardiovascular, respiratory, vasoreceptor and chemoreceptor reflexes, and in the modulation of nociception. The A2 or noradrenergic dorsal medullary cell group lies in the nucleus of the tractus solitarius, vagal nucleus and adjoining parvocellular reticular area. Adrenergic group C1 lies rostral to the A2 cell group. Noradrenergic cell group A4 extends into the lateral pontine tegmentum, along the subependymal surface of the superior cerebellar peduncle. Noradrenergic group A5 forms part of the paragigantocellular nucleus in the caudolateral pontine tegmentum. Noradrenergic cell group A5 and adrenergic cell group C1 probably function as centres of vasomotor control. The entire region is subdivided into functional areas on the basis of stimulation experiments in animals, in which vasoconstrictor, cardioaccelerator, depressor, inspiratory, expiratory and sudomotor effects have been elicited.

The lateral pontine tegmental reticular grey matter is related to the superior cerebellar peduncle and forms the medial and lateral parabrachial nuclei and the ventral Kölliker–Fuse nucleus, a pneumotaxic centre. The locus coeruleus (noradrenergic cell group A6), area subcoeruleus, noradrenergic cell group A7, and cholinergic group Ch5 in the pedunculopontine tegmental nucleus (nucleus tegmenti pedunculopontinus), are all located in the lateral pontine and mesencephalic tegmental reticular zones. The mesencephalic group Ch5 is continuous caudally with cell group Ch6 in the pontine central grey matter.

Cell group A6 contains all the noradrenergic cells in the central region of the locus coeruleus. Group A6 has ventral (nucleus subcoeruleus, A6 Sc), rostral and caudolateral extensions, the latter merging with the A4 group. The locus
coeruleus probably functions as an attention centre, focusing neural functions to prevailing needs. The noradrenergic A7 group occupies the rostroventral part of the pontine tegmentum and is continuous with groups A5 and A1 through the lateral rhombencephalic tegmentum. The A7, A5, A1 complex is also connected by noradrenergic cell clusters with group A2, caudally, and group A6, rostrally. The A5 and A7 groups lie mainly within the medial parabrachial and Kölliker–Fuse nuclei. Reticular neurones in the lateral pontine tegmental reticular area, like those of the ventrolateral zone, function to regulate respiratory, cardiovascular and gastrointestinal activity. Two micturition centres are located in the dorsomedial and ventrolateral parts of the lateral pontine tegmentum.

The connections of the lateral column reticular nuclei are complex. The short ascending and descending axons of the parvocellular reticular area constitute bulbar reflex pathways, which connect all branchiomotor nuclei and the hypoglossal nucleus with central afferent cranial nerve complexes through a propriobulbar system. The area also receives descending afferents from the contralateral motor cortex via the corticotegmental tract, and from the contralateral red nucleus via the rubrospinal tract. The longitudinal catacholamine bundle passes through the parvocellular reticular formation.

The superficial ventrolateral reticular area receives its principal input from the nucleus solitarius, and subserves cardiovascular, baroreceptor, chemoreceptor and respiratory reflexes; it also receives some input from the spinal cord, insular cortex and amygdala. Reticulospinal fibres from the region terminate bilaterally on sympathetic preganglionic neurones in the thoracic spinal cord. Fibres from the pneumotaxic centre project to an inspiratory centre in the ventrolateral part of the nucleus solitarius, and a mixed expiratory–inspiratory centre in the superficial ventrolateral reticular area. Inspiratory neurones in both centres monosynaptically project to the phrenic and intercostal motor neurones. Axons of expiratory neurones terminate on lower motor neurones which innervate intercostal and abdominal musculature.

The superficial ventrolateral area is also the seat of the 'visceral alerting response'. Fibres from the hypothalamus, periaqueductal grey matter and midbrain tegmentum mediate increased respiratory activity, raised blood pressure, tachycardia, vasodilation in skeletal muscle and renal and gastrointestinal vasoconstriction. Ascending efferents from the superficial ventrolateral area synapse on neurones of the supraoptic and paraventricular hypothalamic nuclei. Excitation of these neurones causes release of vasopressin from the neurohypophysis. Medullary noradrenergic cell groups A1 and A2 also innervate (directly and indirectly) the median eminence, and control the release of growth hormone, luteinizing hormone and adrenocorticotropic hormone.
The lateral pontine tegmentum, particularly the parabrachial region, is reciprocally connected to the insular cortex. It shares reciprocal projections with the amygdala through the ventral amygdalofugal pathway, medial forebrain bundle and central tegmental tract, and with hypothalamic, median preoptic and paraventricular nuclei, which preferentially project to the lateral parabrachial nucleus and the micturition centres. It also shares reciprocal bulbar projections, many from the pneumotaxic centre, with the nucleus solitarius and superficial ventrolateral reticular area.

Reticulospinal fibres descend from the lateral pontine tegmentum. A mainly ipsilateral subcoeruleospinal pathway is distributed to all spinal segments of the cord through the lateral spinal funiculus. Crossed pontospinal fibres descend from the ventrolateral pontine tegmentum, decussate in the rostral pons and occupy the contralateral dorsolateral spinal funiculus. They terminate in laminae I, II, V and VI of all spinal segments of the cord. Fibres from the pneumotaxic centre innervate the phrenic nucleus and T1–T3 sympathetic preganglionic neurones bilaterally through this projection system.

Bilateral projections from the micturition centres travel in the lateral spinal funiculus. They terminate on preganglionic parasympathetic neurones in the sacral cord (which innervate the detrusor muscle in the urinary bladder), and on neurones in the nucleus of Onuf (which innervate the musculature of the pelvic floor and the anal and urethral sphincters) (Ch. 75).

Descending fibres of the A6 noradrenergic neurones of the locus coeruleus project into the longitudinal dorsal fasciculus (as the caudal limb of the dorsal periventricular pathway), and into the caudal limb of the dorsal noradrenergic bundle (as part of the longitudinal catecholamine bundle). In this way they innervate, mainly ipsilaterally, all other rhombencephalic reticular areas, principal and spinal trigeminal nuclei, pontine nuclei, cochlear nuclei, nuclei of the lateral lemniscus, and bilaterally, all spinal preganglionic autonomic neurones and the ventral region of the dorsal horn in all segments of the spinal cord. Other axons that contribute to the longitudinal catecholamine bundle originate from cell groups C1, A1, A2, A5 and A7. The main projection is a descending one from cell groups C1 and A5, which are sudomotor neural control centres and innervate preganglionic sympathetic neurones.

Most ascending fibres from the locus coeruleus pass in the dorsal noradrenergic (or tegmental) bundle; others run in either the rostral limb of the dorsal periventricular pathway or in the superior cerebellar peduncle. The latter fibres terminate on the deep cerebellar nuclei. The dorsal noradrenergic bundle is large and runs through the ventrolateral periaqueductal grey matter to join the medial forebrain bundle in the hypothalamus, from where fibres continue forward to innervate all rostral areas of the brain. The pathway contains efferent and afferent axons that reciprocally connect the locus
coeruleus with adjacent structures along its course, e.g. central mesencephalic grey matter, dorsal raphe nucleus, superior and inferior colliculi, interpeduncular nucleus, epithalamus, dorsal thalamus, habenular nuclei, amygdala, septum, olfactory bulb and anterior olfactory nucleus, the entire hippocampal formation and neocortex. Fibres from the locus coeruleus which travel in the rostral limb of the dorsal periventricular pathway, ascend in the ventromedial periaqueductal grey matter adjacent to the longitudinal dorsal fasciculus and terminate in the parvocellular part of the paraventricular nucleus in the hypothalamus.

The functions of the locus coeruleus and related tegmental noradrenergic cell groups are poorly understood. The diversity of their rostral and caudal projections suggests a widespread role in central processing. In animals, firing rates of locus coeruleus neurones peak during wakefulness and decrease during sleep – they cease almost completely during rapid eye movement (REM) sleep. During wakefulness, firing rates are augmented when novel stimuli are presented. The locus coeruleus may, therefore, function to control the level of attentiveness. Other functions that have been ascribed to the locus coeruleus include control of the wake–sleep cycle, regulation of blood flow, and maintenance of synaptic plasticity.

The A1, A2, A5 and A7 noradrenergic cell groups project rostrally, mainly through the central tegmental tract. Their axons constitute a major longitudinal catecholamine pathway that continues through the medial forebrain bundle and ends in the amygdala, lateral septal nucleus, bed nucleus of the stria terminalis, nucleus of the diagonal band and the hypothalamus. The ascending dorsal periventricular pathway contains a few non-coerulean noradrenergic fibres, which terminate in the periventricular region of the thalamus.

Propriobulbar projections receive a contribution from the diffusely organized dorsal medullary and lateral tegmental noradrenergic cell groups. These interconnect cranial nerve nuclei and other reticular cell groups, particularly those of the vagus, facial and trigeminal nerves, and the rhombencephalic raphe and parabrachial nuclei.

Three precerebellar nuclei, the lateral and paramedian reticular nuclei and the nucleus of the pontine tegmentum, are involved in the relay of spinal information into the vermis and paravermal regions of the ipsilateral cerebellar hemisphere. They receive inputs from the contralateral primary motor and sensory neocortices, and the ipsilateral cerebellar and vestibular nuclei and spinal cord (the latter through the ascending spinoreticular pathway). This system augments the dorsal and ventral spinocerebellar, cuneocerebellar, accessory cuneocerebellar and trigeminocerebellar tracts.
Unilateral brain stem lesions (Fig. 19.21, Fig. 19.22) may arise as a result of extrinsic compression of the brain stem by space occupying tumours (e.g. meningioma, acoustic neuroma or metastatic carcinoma) or may be caused by intrinsic disease (e.g. glioma, demyelination or stroke). The clinical syndrome is determined by the neuroanatomical site of the lesion. At the segmental level, an ipsilateral cranial nerve palsy occurs. Below the level of the lesion, there is a contralateral loss of power and sensation in the limbs (corresponding to dysfunction of the decussating corticospinal and ascending sensory pathways), and ipsilateral incoordination of the limbs (as a result of the interruption of efferent and afferent cerebellar connections).
The ipsilateral cranial nerve dysfunction reflects the segmental level of the lesion in the midbrain, pons and medulla. Midbrain lesions cause ophthalmoplegia, pupillary dilatation and ptosis (oculomotor nerve palsy) and impaired upward gaze (e.g. due to a pinealoma). Pontine lesions (e.g. an acoustic neuroma in the cerebellopontine angle) lead to ophthalmoplegia (abducens nerve lesion), loss of facial sensation and weakness of masticatory muscles (trigeminal nerve lesion), weakness of facial muscles (facial nerve lesion), deafness and vertigo (vestibulocochlear nerve lesion). Medullary lesions cause a ‘bulbar palsy’, i.e. dysarthria, dysphagia and dysphonia, with wasting of the hemi-tongue and palate (glossopharyngeal, vagal and hypoglossal nerve lesions) and weakness and wasting of sternocleidomastoid and trapezius (accessory nerve lesion).
In addition to this focal brain stem syndrome, blockage of the outflow of CSF from the fourth ventricle via the foramina of Magendie and Luschka (e.g. by extrinsic tumours) produces hydrocephalus, which is characterized by headache, papilloedema and progressive stupor and coma.

Bilateral destructive lesions of the brain stem are fatal if untreated, because of damage to ‘centres’ in the medulla that control respiration, heart rate and blood pressure. Impairment of the reticular activating system in the core of the brain stem leads to progressive impairment of consciousness, followed by stupor and coma. In this state of ‘brain stem death’, life can only be supported artificially. This is the fate of all untreated expanding space-occupying lesions in the cranium (e.g. haematoma, abscess, tumour, whether extrinsic or intrinsic to the brain, and cerebral oedema). A space-occupying lesion within the unyielding skull raises the intracranial pressure directly and also indirectly by obstruction of CSF flow, which causes headache and papilloedema. The brain is distorted and displaced downward (rostro-caudally) within the skull and meningeal framework. The brain stem is vulnerable to compression at two critical sites, which are determined by the neuroanatomical relationship of the meningeal tentorium and foramen magnum to the cerebral hemisphere (supratentorial) and brain stem (infratentorial). The downward displacement of the cerebral hemisphere leads to herniation of the ipsilateral medial temporal lobe (uncus) through the tentorial notch. There may be direct ipsilateral compression of the midbrain and emergent oculomotor and trochlear cranial nerves or contralateral compression of the upper brain stem by the abutting sharp edge of the tentorium. The ipsilateral posterior cerebral artery is vulnerable to compression at this site. Unilateral herniation is heralded by a progressive oculomotor nerve palsy (ophthalmoplegia, pupillary dilatation and ptosis), contralateral limb weakness, falling level of consciousness, and, if treatment is long delayed, a contralateral homonymous hemianopia. Compression of the contralateral brain stem by the tentorium leads to ipsilateral ‘false localizing’ signs.

Further progressive rostro-caudal displacement of the brain ultimately leads to herniation of the medulla through the foramen magnum and into the spinal canal. This is accompanied by bilateral cranial nerve dysfunction, quadriplegia, deepening coma and finally apnoea, i.e. brain stem death. These neuroanatomical and functional processes underlie the diagnosis and management of the traumatically brain injured patient, and the complications of intracranial haematomas (extradural, subdural and intracerebral) and cerebral oedema.

CHAPTER 20 – Cerebellum

The cerebellum occupies the posterior cranial fossa, separated from the occipital lobes of the cerebral hemispheres by the tentorium cerebelli. It is the largest part of the hindbrain; in adults the weight ratio of cerebellum to cerebrum is approximately 1 : 10 and in infants 1 : 20. The cerebellum lies dorsal to the pons and medulla, from which it is separated by the fourth ventricle. It is joined to the brain stem by three bilaterally paired cerebellar peduncles, and these contain all the afferent and efferent fibres associated with the cerebellum.

The basic internal organization of the cerebellum is of a superficial cortex overlying a dense core of white matter. The cortex is highly convoluted, forming narrow ridges, or folia, and intervening sulci and fissures. Aggregations of neuronal cell bodies embedded within the white matter constitute the fastigial, globose, emboliform and dentate nuclei – collectively known as the (deep) cerebellar nuclei. In general terms, the majority of afferent input to the cerebellum terminates in the cortex. The output from the cortex is carried by the axons of cortical Purkinje cells; most of these axons terminate in the deep cerebellar nuclei which are themselves the major origin of cerebellar efferent projections.

The cerebellum is an important part of the circuitry that links sensory to motor areas of the brain, and it functions to coordinate movement. It provides corrections during movement, which are the basis for precision and accuracy, and it is critically involved in motor learning and reflex modification. It receives information from peripheral receptors through spinal, trigeminal and vestibulocerebellar pathways and from the cerebral cortex and the tectum, via the intermediary of pontine nuclei. Cerebellar output is directed predominantly to the thalamus and thence to the motor cortex, and also to brain stem centres such as the red nucleus, vestibular nuclei and reticular nuclei that themselves give rise to descending spinal pathways.

EXTERNAL FEATURES AND RELATIONS

The cerebellum consists of two large, laterally located hemispheres which are united by a midline vermis (Figs 20.1, 20.2, 20.3). The superior surface of the cerebellum, which would constitute the anterior part of the unrolled cerebellar cortex, has a flat profile (Fig. 20.3). The paramedian sulci are shallow and the borders between vermis and hemispheres are indicated by kinks in the transverse fissures. The superior surface adjoins the tentorium cerebelli and projects beyond its free edge. The transverse sinus borders the cerebellum at the point where the superior and inferior surfaces meet. The inferior surface is characterized by a massive enlargement of the cerebellar hemispheres, which extend medially to overlie some of the vermis. Deep paramedian sulci demarcate the vermis from the hemispheres. Posteriorly the hemispheres are separated by a deep vallecula, which contains the dural falx cerebelli. The inferior cerebellar surface lies against the occipital squama. The shape of the surface facing the brain stem is irregular and forms the roof of the fourth ventricle and the lateral recesses on each side of it, while the cerebellar peduncles define the diamond shape of the ventricle when viewed from behind. Anterolaterally the cerebellum lies against the posterior surface of the petrous part of the temporal bone.

The cerebellar surface is divided by numerous curved transverse fissures which separate its folia and give it a laminated appearance. The deepest fissures divide it into lobes and lobules. One conspicuous fissure, the horizontal fissure, extends around the dorsolateral border of each hemisphere from the middle cerebellar peduncle to the vallecula, separating the superior and inferior surfaces. Although the horizontal fissure is prominent, it appears relatively late in embryological development and does not mark the boundary between major functional subdivisions of the cortex. The deepest fissure in the vermis is the primary fissure, which curves ventrolaterally around the superior surface of the cerebellum to meet the horizontal fissures; it appears early in embryological development and marks the boundary between the anterior and posterior lobes.

Because the cerebellar cortex has a roughly spherical shape, the true relationships between its parts is somewhat obscure. Thus, the most anterior lobule of the cerebellar vermis, the lingula, lies very close to the most posterior lobule, the nodule. The lobules of the superior vermis that belong to the anterior lobe are the lingula, central lobule and culmen. The lingula is a single lamina of four or five shallow folia. Its white core is continuous with the superior medullary velum, and it is separated from
the central lobule by the precentral fissure. The central lobule and culmen are continuous bilaterally with an adjoining lateral extension, or wing, in each hemisphere. The central lobule is separated from the culmen by the preculminary fissure. The culmen (with attached anterior quadrangular lobules) lies between the preculminary and primary fissures.

The simple lobule (with attached posterior quadrangular lobules) and the folium (with attached superior semilunar lobules) lie between the primary and the horizontal fissures: the two lobule sets are separated by the posterior superior fissure.

From the back forward, the inferior vermis is divided into the tuber, pyramis, uvula and nodule, in that order. The tuber is continuous laterally with the inferior semilunar lobules and separated from the pyramis by the lunogracile fissure. The pyramis and attached biventral lobules (containing an intrabiventral fissure) are separated from the uvula and attached cerebellar tonsils by the secondary fissure. Behind the uvula, and separated from it by the median part of the posterolateral fissure, is the nodule. The tonsils are roughly spherical and overhang the foramen magnum on each side of the medulla oblongata.

The nodule and attached flocculi constitute a separate flocculonodular lobe, which is separated from the uvula and tonsils by the deep posterolateral fissure. The flocculonodular lobe is richly interconnected with the vestibular nuclei, which lie at the lateral margin of the fourth ventricle.

**FUNCTIONAL DIVISIONS OF THE CEREBELLUM**

Functionally speaking, the cerebellum can be divided into a body, with inputs mainly from the spinal cord and pontine nuclei, and a flocculonodular lobe, which has strong afferent and efferent connections with the vestibular nuclei (Fig. 20.4). The body is subdivided into a series of regions dominated by their spinal or pontine inputs. The anterior lobe, simple lobule, pyramis and biventral lobules are the main recipients of spinal and trigeminal cerebellar afferents. Pontocerebellar input dominates in the folium, tuber and uvula, and throughout the entire hemisphere, including those regions that receive afferents from the spinal cord.
The mediolateral subdivision of the cerebellum into vermis and hemispheres represents a functional subdivision that is closely related to its output. In mammals, the increase in the size of the cerebellar hemispheres parallels the development of the cerebral cortex, and reflects the importance of the corticopontocerebellar input and of the efferent projections of the cerebellar hemispheres (through the dentate, emboliform and globose nuclei) to the thalamus and thence to the cerebral cortex.
INTERNAL STRUCTURE

The vast majority of cerebellar neuronal cell bodies are located within the outer, highly convoluted cortical layer. Beneath the cortex, the cerebellar white matter forms an extensive central core from which a characteristic branching pattern of nerve fibres (arbor vitae) extends towards the cortical surface. The white matter consists of afferent and efferent fibres travelling to and from the cerebellar cortex. Fibres crossing the midline in the white core of the cerebellum and the anterior medullary velum effectively constitute a cerebellar ‘commissure’; the afferent portion contains fibres of the restiform body and the middle cerebellar peduncle, and the efferent portion contains decussating fibres from the fastigial nucleus.

CEREBELLAR NUCLEI

Laterally, on either side within the white matter core, are four cerebellar nuclei. These are the dentate, emboliform, globose and fastigial nuclei. The dentate nucleus, which is located most laterally and is by far the largest, is the only nucleus easily visible to the naked eye (Fig. 20.1). It has the form of an irregularly folded sheet of neuronal cell bodies, with a medially directed hilum through which pass a mass of fibres mainly derived from dentate neurones and which form the bulk of the superior cerebellar peduncle. The emboliform and globose nuclei lie medial to the dentate and are equated to the nucleus interpositus (interposed nucleus) in lower species; the emboliform and globose nuclei may sometimes be referred to as the anterior and posterior interposed nuclei, respectively. Their efferent fibres join the superior cerebellar peduncle. The fastigial nucleus lies next to the midline, bordering on the roof of the fourth ventricle. A large proportion of the efferent fibres that leave this nucleus decussate within the cerebellar white matter and subsequently constitute the uncinate fasciculus, which passes dorsal to the superior cerebellar peduncle to enter the contralateral vestibular nuclei. Uncrossed fastigiobulbar fibres enter the vestibular nuclei by passing along the lateral angle of the fourth ventricle, and some fibres of the fastigial nucleus ascend in the superior cerebellar peduncle.
**CEREBELLAR PEDUNCLES**

Three pairs of peduncles connect the cerebellum with the brain stem (see Ch. 19; Fig. 20.5).

![Dissection of the left cerebellar hemisphere and its peduncles.](image)

The middle cerebellar peduncle is the most lateral and by far the largest of the three. It passes obliquely from the basal pons to the cerebellum and is composed almost entirely of fibres that arise from the contralateral basal pontine nuclei, with a small addition from nuclei in the pontine tegmentum.

The inferior cerebellar peduncle is located medial to the middle peduncle. It consists of an outer, compact fibre tract, the restiform body, and a medial, juxtarestiform body. The restiform body is a purely afferent system; it receives the posterior spinocerebellar tract from the spinal cord and the trigeminocerebellar, cuneocerebellar, reticulocerebellar and olivocerebellar tracts from the medulla oblongata. The juxtarestiform body is mainly an efferent system; it is made up almost entirely of efferent Purkinje cell axons from the vestibulocerebellum, on their way to the vestibular nuclei, and uncrossed fibres from the fastigial nucleus. It also contains primary afferent fibres travelling in the vestibular nerve and secondary afferent fibres from the vestibular nuclei. The crossed fibres from the fastigial nucleus pass dorsal to
the superior cerebellar peduncle and enter the brain stem as the uncinate fasciculus at the border of the juxtarestiform and restiform bodies.

The superior cerebellar peduncle contains all of the efferent fibres from the dentate, emboliform and globose nuclei and a small fascicle from the fastigial nucleus. Its fibres decussate in the caudal mesencephalon, on their way to synapse in the contralateral red nucleus and thalamus. The anterior spinocerebellar tract reaches the upper part of the pontine tegmentum before looping down within this peduncle to join the spinocerebellar fibres entering through the restiform body.
CEREBELLAR CORTEX

Although the human cerebellum makes up approximately one-tenth of the entire brain by weight, the surface area of the cerebellar cortex, if unfolded, would be about half that of the cerebral cortex. The great majority of cerebellar neurones are small granule cells, so densely packed that the cerebellar cortex contains many more neurones than the cerebral cortex. Unlike the cerebral cortex, where a large number of diverse cell types are arranged differently in different regions, the cerebellar cortex contains a relatively small number of different cell types, which are interconnected in a highly stereotyped way. As a consequence, all regions of the cerebellar cortex look similar in histological sections.

The elements of the cerebellar cortex possess a precise geometric order, which is arrayed relative to the tangential, longitudinal and transverse planes in individual folia. The cortex contains the terminations of afferent ‘climbing’ and ‘mossy’ fibres, five varieties of neurone (granular, stellate, basket, Golgi and Purkinje), neuroglia and blood vessels.

There are three main layers: molecular, Purkinje cell and granular (Fig. 20.6). The main circuit of the cerebellum involves granule cells, Purkinje cells and neurones in the cerebellar nuclei. Granule cells receive the terminals of the mossy fibre afferents (i.e. all afferent systems except the olivocerebellar fibres). The axons of the granule cells ascend to the molecular layer, where they bifurcate into parallel fibres, which are so called because they are oriented parallel to the transverse fissures and perpendicular to the dendritic trees of the Purkinje cells on which they terminate. Purkinje neurones are large and are the sole output cells of the cerebellar cortex. Their axons terminate in the cerebellar nuclei and in the vestibular nuclei. In addition to the dense array of parallel fibres, the dendritic trees of Purkinje cells receive terminals from climbing fibres which originate from neurones in the inferior olivary nucleus. The cerebellar cortex thus receives two distinct types of input: olivocerebellar climbing fibres, which synapase directly on Purkinje neurones, and mossy fibres, which connect to the Purkinje cells via granular neurones, whose axons are the parallel fibres.
Fig. 20.6 The general organization of the cerebellar cortex. A single folium has been sectioned vertically, both in its longitudinal axis (right part of diagram) and transversely.

Both parallel and climbing fibres excite the Purkinje cells, but they differ greatly in their firing characteristics and their effect on them. Purkinje cell axons inhibit their target neurones in the cerebellar nuclei; the latter project to motor control centres in the brain stem and cerebrum. The stellate, basket and Golgi cells are inhibitory interneurones and connect the cortical elements in complex geometrical patterns.

The molecular layer is approximately 300–400 µm thick. It contains a sparse population of neurones, dendritic arborizations, non-myelinated axons and radial fibres of neuroglial cells. Purkinje cell dendritic trees extend towards the surface and spread out in a plane perpendicular to the long axis of the cerebellar folia. Purkinje cell dendrites are flattened. The lateral extent of the Purkinje cell dendrites is some 30 times greater in the transverse plane than it is in a plane parallel to the cerebellar folia. Parallel fibres are the axons of granule cells, the stems of which ascend into the molecular layer where they bifurcate at T-shaped branches. The two branches extend in opposite directions as parallel fibres along the axis of a folium. Parallel fibres terminate on the dendrites of the Purkinje cells and Golgi cells, which they pass on their way, and on the basket and stellate cells of the molecular layer. Dendritic trees of Golgi neurones reach towards the surface. Unlike the flattened dendritic tree of the Purkinje cell, Golgi cell dendrites span the territory of many Purkinje neurones longitudinally as well as transversely. These dendrites receive synapses from parallel fibres. Some Golgi cell dendrites enter the granular layer, where they contact mossy fibre terminals. The cell bodies of Golgi neurones lie below, in the superficial part of the granular layer. The molecular layer also contains the somata, dendrites and axons of stellate neurones (which are located superficially within the molecular layer) and of basket cells (whose somata lie deeper within the molecular layer). Climbing fibres, the terminals of olivocerebellar fibres, ascend through the granular layer to contact Purkinje dendrites in the molecular layer. Radiating branches from large epithelial (Bergmann) glial cells give off processes that surround all neuronal elements, except at the synapses. Their conical expansions join to form an external limiting membrane.
at the surface of the cerebellum.

The Purkinje cell layer contains the large, pear-shaped somata of the Purkinje cells and the smaller somata of Bergmann glia. Clumps of granule cells and occasional Golgi cells penetrate between the Purkinje cell somata.

The granular layer (Fig. 20.6) is about 100 µm thick in the fissures and 400–500 µm on foliar summits. There are approximately 2.7 million granular neurones per cubic millimetre. It has been estimated that the human cerebellum contains a total of $4.6 \times 10^{10}$ granule cells, and that there are 3000 granule cells for each Purkinje cell.

In summary, the granular layer consists of the somata of granule cells and the initial segment of their axons; dendrites of granule cells; branching terminal axons of afferent mossy fibres; climbing fibres passing through the granular layer *en route* to the molecular layer; and the somata, basal dendrites and complex axonal ramifications of Golgi neurones. Cerebellar glomeruli are synaptic rosettes consisting of a mossy fibre terminal that forms excitatory synapses upon the dendrites of both granule cells and Golgi cells.

Of the five cell types to be described, the first four are inhibitory, liberating γ-aminobutyric acid (GABA), and the fifth is excitatory, liberating L-glutamate. Figure 20.7 summarizes their main connections.
Purkinje cells have a specific geometry, which is conserved in all vertebrate classes (Fig. 20.6). They are arranged in a single layer between the molecular and granular layers. Individual Purkinje cells are separated by about 50 µm transversely and 50–100 µm longitudinally. Their somata measure approximately 50–70 µm vertically and 30–35 µm transversely. The subcellular structure of the Purkinje cell is similar to that of other neurons. One distinguishing feature is subsurface cisterns, often associated with mitochondria, which are present below the plasmalemma of somata and dendrites and may penetrate into the spines. The cisterns are intracellular calcium stores which are important links in the second messenger systems of the cell.

One, sometimes two, large primary dendrites arise from the outer pole of a Purkinje cell. From these an abundant arborization, with several orders of subdivision, extends towards the surface. Branches of each neurone are confined to a narrow sheet in a plane transverse to the long axis of the folium. Proximal first- and second-order dendrites have smooth surfaces with short, stubby spines, and are contacted by climbing fibres. Distal branches show a dense array of dendritic spines, which receive synapses from the terminals of parallel fibres. Inhibitory synapses are received from basket and stellate cells and from the recurrent collaterals of Purkinje cell axons, which contact the shafts of the proximal dendrites. The total number of dendritic spines per Purkinje neurone is in the order of 180,000.

The axon of a Purkinje cell leaves the inner pole of the soma and crosses the granular layer to enter the subjacent white matter. The initial axon segment receives axo-axonic synaptic contacts from distal branches of basket cell axons. Beyond the initial segment, the axon enlarges, becomes myelinated, and gives off collateral branches. The main axon ultimately forms a plexus in one of the cerebellar or vestibular nuclei. The recurrent collateral branches end on other Purkinje cells and on basket and Golgi neurones.

Basket and stellate cells are the neurones of the molecular layer. Their sparsely branched dendritic trees and the ramifications of their axons lie in a plane approximately perpendicular to the long axis of the folium, i.e. in the same plane as the Purkinje cell dendritic tree. Stellate cells are located in the superficial molecular layer and their axons synapse with the shafts of Purkinje cell dendrites. Both stellate and basket cells receive excitatory synapses from parallel fibres passing through their dendritic tree. Basket cells lie in the lower third of the molecular layer. Their somata
receive synapses from Purkinje cell recurrent collaterals, climbing and mossy fibres as well as from the parallel fibres. Basket cell axons increase in size away from their somata and run deep in the molecular layer just above the Purkinje cells. Continuing for about 1 mm, each covers the territories of 10 to 12 Purkinje neurones. Collaterals of the basket cell axons ascend along Purkinje cell dendrites, and descend towards Purkinje cell somata and initial axonal segments forming pericellular networks, or ‘baskets’, around them. Branches from each basket cell axon also extend in the direction of the long axis of the folium to a further 3 to 6 rows of Purkinje neurones, flanking the axon. It follows that around 70 Purkinje cell neurones may receive synapses from a single basket neurone.

Most Golgi cell somata occupy the superficial zone of the granular layer, adjoining the Purkinje cell somata. Their dendrites radiate into the molecular layer. Unlike Purkinje cells, the dendritic trees of Golgi cells are not flattened, appearing much the same in transverse and longitudinal foliar section. In both planes they overlap the territories of several neighbouring Purkinje and Golgi cells. Some Golgi dendrites, however, divide in the granular layer and join cerebellar glomeruli, where they receive excitatory synaptic contacts from mossy fibres. The axon of the Golgi cell arises from the base of the cell body or proximal dendrite and immediately divides into a profuse arborization which extends through the entire thickness of the granular layer. The territory occupied by the axonal ramifications is of a volume that corresponds approximately to its dendritic tree in the molecular layer, and which overlaps with the axonal arborizations of adjacent Golgi cells. The main synaptic input to Golgi cell dendrites is from parallel fibres in the molecular layer. Purkinje cell recurrent collaterals and mossy and climbing fibres also terminate on their proximal dendrites and, more sparsely, on their somata.

Each granule cell has a spherical nucleus, 5–8 µm in diameter, with a mere shell of cytoplasm containing a few small mitochondria, ribosomes and a diminutive Golgi complex. Granule cells give rise to 3 to 5 short dendrites, which end in claw-like terminals within the synaptic glomeruli. The fine axons of granule cells enter the molecular layer and branch at a T-junction to form parallel fibres passing in opposite directions over a distance of several millimetres. Terminals located along the parallel fibres give them a beaded appearance and are sites of synapses upon the dendrites of Purkinje, stellate, basket and Golgi cells in the molecular layer. Most numerous are the synapses with Purkinje dendritic spines. It had been estimated that about 250,000 parallel fibres cross a single Purkinje dendritic tree, although every parallel fibre may not synapse with each dendritic tree that it crosses.

Two very different excitatory inputs innervate the cerebellar cortex, namely climbing fibres and mossy fibres.

Climbing fibres arise only from the inferior olivary nucleus. Olivocerebellar fibres cross the white matter and enter the granular layer where they branch to form climbing fibres. Each climbing fibre innervates a single Purkinje cell. There are about ten times as many Purkinje cells as there are cells in the inferior olive and so each olivocerebellar fibre branches into about 10 climbing fibres. Individual climbing fibres pass alongside the soma of a Purkinje cell, and then branch to make numerous synapses on the short, stubby spines that protrude from the proximal segments of Purkinje cell dendrites.
Mossy fibres take their origin from the spinal cord, the trigeminal, dorsal column, and reticular nuclei of the medulla, and the pontine tegmentum and basal pons. Like climbing fibres they are excitatory, but they contrast sharply in their anatomical distribution and physiological properties. As each mossy fibre traverses the white matter its branches diverge to enter several adjacent folia. Within each folium these branches expand into grape-like synaptic terminals (mossy fibre rosettes), which occupy the centre of cerebellar glomeruli.

Noradrenergic and serotoninergic fibres form a rich plexus in all layers of the cerebellar cortex. The aminergic fibres are fine, varicose and form extensive cortical plexuses: their release of noradrenaline and serotonin is assumed to be non-synaptic, and their effects paracrine, involving volumes of tissue. The serotoninergic afferents of the cerebellum take their origin from neurones in the medullary reticular formation, other than the raphe nuclei. The noradrenergic, coeruleocerebellar projection, when active, inhibits Purkinje cell firing not by direct action but via β-adrenergic-receptor-mediated inhibition of adenylate cyclase in the Purkinje cells. Cerebellar afferents have been traced from dopaminergic cells in the ventral tegmental area, and dopamine D2 and D3 receptors are present in the molecular layer. A plexus of thin, ChAT-containing fibres is centred on the Purkinje cell layer. The cells of origin of these cholinergic fibres are not known.

The connections of the cerebellum are organized in two perpendicular planes, corresponding to the planar organization of the cerebellar cortex. Efferent connections of the cortex are disposed in parasagittal sheets or bundles, which connect longitudinal strips of Purkinje cells with specific cerebellar or vestibular nuclei. The climbing fibre afferents to a Purkinje cell zone from the inferior olive display a similar zonal disposition. Cerebellar output is organized in modules, where a module consists of one or more Purkinje cell zones, their cerebellar or vestibular target nucleus, and their olivocerebellar climbing fibre input. Modular function is determined by the brain stem projections of the cerebellar or vestibular target nucleus. A general feature of the modular organization of the cerebellum is that GABAergic neurones in the cerebellar nuclei project to the subnuclei of the contralateral inferior olive, which give rise to their respective climbing fibre afferents. These recurrent connections are known as nucleo-olivary pathways.

Mossy fibre afferent systems from precerebellar nuclei in the spinal cord and the brain stem terminate in the granular layer of certain lobules in transversely oriented terminal fields. The transverse lobular arrangement of the mossy fibre afferents is enforced by the transverse orientation of the parallel fibres, which are axons of the granule cells and constitute the second link in the mossy fibre–parallel fibre input of the Purkinje cells. Parallel fibres cross and terminate on Purkinje cells belonging to several successive modules as they course through the molecular layer.

Purkinje cells can be activated in two different ways. Granule cell activity generates simple spikes, which resemble the response of other neurones in the brain, whereas activation by a climbing fibre produces a prolonged depolarization upon which several spike-like waves are superimposed. The rate of firing of single and complex spikes also differs markedly. While the Purkinje cell may fire simple spikes at a rate of hundreds per second, complex spikes occur at low frequencies, seldom more than three or four per second.
Purkinje cell activity is regulated by local Golgi, basket and stellate cells. Like Purkinje cells, Golgi cells have a rich dendritic tree that extends through the molecular layer. Unlike Purkinje cells, the Golgi cell dendrites are not restricted to a plane transverse to the folia and their axons do not leave the cerebellar cortex. Golgi cells regulate firing by presynaptic inhibition of the mossy fibre afferents, and so act as a governor, or rate limiter, of Purkinje cell activity. Stellate and basket cells synapse directly on Purkinje cells and are powerful inhibitors of their activity.

**Structural and functional cerebellar localization**

Since the cerebellar cortex is largely uniform in microstructure and microcircuitry, it seems likely that its basic mode of operation is also uniform. The most obvious input for this operation is provided by the mossy fibre afferents, which carry information from all levels of the spinal cord, and specialized sensory and motor information relayed from the cerebral cortex and subcortical motor centres. The most obvious output from the cerebellum is directed at motor systems. Purkinje cells are organized in modules, i.e. discrete, parallel zones that converge upon different cerebellar output nuclei coupled to different motor systems in the brain stem, spinal cord and cerebral cortex. Cerebellar function is therefore determined by temporal and spatial factors, e.g. inhibitory interneurones of the cerebellar cortex, which regulate the access of a particular combination of mossy fibre–parallel fibre inputs to an appropriate output. Plastic changes in the response properties of Purkinje cells, in the form of long-term depression of the parallel fibre–Purkinje cell synapses, may also contribute. Short-term and long-term changes in the response properties of Purkinje cells are under the influence of the climbing fibres.

A double, mirrored, localization exists in the anterior and posterior cerebellum (Fig. 20.8). The anterior lobe, simple lobule, pyramid and the adjoining lobules of the hemisphere of the posterior lobe all receive branches from the same mossy and climbing fibres and project to the same cerebellar nuclei. The efferent pathways of these regions monitor the activity in the corticospinal tract and in the subcortical motor systems descending from the vestibular nuclei and reticular formation. The inputs to the cerebellum and the outputs from it are organized according to the same somatotopical patterns, but the orientation of these patterns is reversed. The representation of the head is found principally in the simple lobule, and caudally in a corresponding region of the posterior lobe. The double representation of the body follows in rough somatotopic order. Vestibular connections of the cerebellum display a similar double representation in the most rostral lobules of the anterior lobe and far caudally in the vestibulocerebellum (Fig. 20.9).
Fig. 20.8  Somatotopic localization in the cerebellar cortex.
The folium, tuber, uvula, tonsil and posterior biventral lobule all receive an almost pure pontine mossy fibre input. Climbing fibres from the inferior olive and mossy fibres from the basilar and tegmental pontine nuclei relay visual and acoustic information from the respective cerebral association areas and midbrain tectum to the folium and tuber thought to represent a vermal visual/acoustic area (Fig. 20.8). The efferent connections of this area travel via the fastigial nucleus to gaze centres in the pons and midbrain.
AFFERENT CONNECTIONS OF THE CEREBELLUM

Mossy fibres and climbing fibres carry the afferent connections of the cerebellum. Mossy fibre systems terminate bilaterally in transversely oriented ‘lobular’ areas; there is considerable overlap amongst the terminations. Climbing fibres from different subnuclei of the inferior olive terminate contralaterally, on discrete longitudinal strips of Purkinje cells. This longitudinal pattern closely corresponds with the zonal arrangement in the corticonuclear projection (Fig. 20.10).

Fig. 20.10  Cerebellar corticonuclear and corticovestibular projections. The widespread projection from
**Spinocerebellar and trigeminocerebellar fibres**

The spinal cord is connected to the cerebellum through the spinocerebellar and cuneocerebellar tracts and through indirect mossy fibre pathways relayed by the lateral reticular nucleus in the medulla oblongata. These pathways are all excitatory in nature and give collaterals to the interposed and fastigial nuclei before ending on cortical granule cells.

The posterior spinocerebellar tract takes its origin from the cells of Clarke's column at the base of the dorsal horn in all thoracic segments of the spinal cord (Fig. 20.11). It enters the inferior cerebellar peduncle, gives collaterals to the cerebellar nuclei, and terminates, mainly ipsilaterally, in the vermis and adjoining regions of the anterior lobe and in the pyramis and adjoining lobules of the posterior lobe. Clarke's column receives primary afferents of all kinds from the muscles and joints of the lower limbs, which reaches the nucleus via the fasciculus gracilis. It also receives collaterals from cutaneous sensory neurones. Accordingly, the tract transmits proprioceptive and exteroceptive information about the ipsilateral lower limb. Very fast conduction is required to keep the cerebellum informed about ongoing movements. The axons in the posterior spinocerebellar tract are the largest in the CNS, measuring 20 µm in diameter. The upper limb equivalent of the posterior spinocerebellar tract is the cuneocerebellar tract.
The anterior spinocerebellar tract is a composite pathway. It informs the cerebellum about the state of activity of spinal reflex arcs related to the lower limb and lower trunk. Its fibres originate in the intermediate grey matter of the lumbar and sacral segments of the spinal cord (Fig. 20.11). They cross near their origin, and ascend close to the surface as far as the lower midbrain before looping down in the superior cerebellar peduncle. Most fibres cross...
again in the cerebellar white matter. Thus their distributions to the cerebellar nuclei and cortex appear to be the same as those of the posterior tract.

The rostral spinocerebellar tract originates from cell groups of the intermediate zone and horn of the cervical enlargement. Although considered to be the upper limb and upper trunk counterpart of the anterior spinocerebellar tract, most of its fibres remain ipsilateral throughout their course. It enters the inferior cerebellar peduncle and terminates in the same cerebellar nuclei and folia as the cuneocerebellar tract.

The cuneocerebellar tract contains exteroceptive and proprioceptive components which originate from the cuneate and external cuneate nuclei respectively. The primary afferents travel in the fasciculus cuneatus. The tract itself is predominantly uncrossed and ends in the posterior half of the anterior lobe. Exteroceptive and proprioceptive mossy fibre components of the tract terminate differentially in the apical and basal part of the folia. The exteroceptive component overlaps the pontocerebellar mossy fibre projection in the apices of the folia of the anterior lobe.

Comparable sets of ipsilateral proprioceptive and interceptive cerebellar projections exist for the extensive territory of the trigeminal brain stem nuclei. These nuclei also project to the ipsilateral inferior olive, relaying from there to the contralateral cerebellar cortex and deep nuclei. The cortical representation of the head is directly behind the primary fissure.

Olivocerebellar fibres

Localization in the olivocerebellar system: zones and microzones

Climbing fibres originate exclusively from subnuclei of the contralateral inferior olivary complex and terminate on longitudinal strips of Purkinje cells in the cerebellar cortex; their collaterals end on the cerebellar or vestibular target nuclei of these Purkinje cells. A longitudinal zonal arrangement is therefore characteristic of the organization of the olivocerebellar projection. Moreover, the olivocerebellar projection zones correspond precisely to the corticonuclear projection zones already described (Fig. 20.10). Climbing fibres from the inferior olive are able to modify the cerebellar output in such a way that cells within each subnucleus of the inferior olivary complex monitor the output of a single cerebellar module.

The inferior olivary complex and its climbing fibres can be activated by tactile, proprioceptive, visual and vestibular stimulation, and from the sensory, motor and visual cortices and their brain stem relays. A somatotopic arrangement of body parts, matching the olivary projections on to the cerebellar cortex, has been described in animals.
Olivocerebellar climbing fibre connections

The inferior olivary complex can be subdivided into a convoluted principal olivary nucleus, and posterior and medial accessory olivary nuclei. Olivary fibres form the olivocerebellar projection to the contralateral cerebellar cortex, and give off collaterals to the lateral vestibular nucleus and to the cerebellar nuclei. Climbing fibres terminate on longitudinal strips of Purkinje cells. The zonal patterns of the olivocerebellar and Purkinje–nuclear projections correspond precisely. The accessory olivary nuclei project to the vermis and the adjacent hemispheres. The caudal halves of the posterior and medial accessory nuclei innervate the vermis. The caudal part of the posterior accessory nucleus projects to Deiters' nucleus and to the B zone of the anterior vermis. The caudal half of the medial accessory olive gives rise to a projection to the fastigial nucleus and provides climbing fibres to the A zone. The rostral halves of the accessory olives project to the pars intermedia. Climbing fibres from the rostral dorsal accessory olive give collateral projections to the emboliform nucleus and terminate in zones C1 and C3. Zone C2 receives terminals from the rostral medial accessory olive, which provides a collateral projection to the globose nucleus. The principal nucleus projects to the contralateral hemisphere (D zone), and gives collaterals to the dentate nucleus.

The inferior olivary complex receives afferent connections from the spinal cord and from sensory relay nuclei in the brain stem, including the posterior column and sensory trigeminal nuclei. It also receives descending connections from the superior colliculus, parvicellular red nucleus and related nuclei in the midbrain and a GABAergic projection, mainly crossed, from the cerebellar nuclei and certain vestibular nuclei. The latter two connections are topically organized. Thus, the dentate nucleus projects to the principal nucleus, the emboliform nucleus to the rostral posterior accessory nucleus, and the globose nucleus to the rostral medial accessory nucleus. The fastigial nucleus is connected with the caudal medial accessory olive, but the fibres are less numerous. The caudal posterior accessory olive receives a projection from the lateral vestibular nucleus.

The posterior accessory olive and the caudal half of the medial accessory olive receive an input from the spinal cord and sensory relay nuclei. The middle region of the medial accessory olive receives a projection from the superior colliculus and projects to folium and vermis. The parvocellular red nucleus and related nuclei project to the olive through the ipsilateral descending central tegmental tract, which terminates in the rostral half of the medial accessory olive and the principal olive. The parvocellular red nucleus receives converging projections from the cerebellar nuclei and from the motor and premotor cortex. Direct pathways from the cerebral cortex to the inferior olive are sparse. The indirect pathways via the parvicellular red nucleus are much larger.
Climbing fibres that terminate in the vestibulocerebellum (flocculus and nodule) are derived from neurones of the medial accessory olive which receive a strong descending afferent connection from optokinetic centres in the midbrain. Optokinetic information is used by the flocculus in long-term adaptation of compensatory eye movements. Neighbouring neurones are under vestibular control and project to the nodule and the adjoining uvula.

**Vestibulocerebellar fibres**

Primary vestibulocerebellar mossy fibres are fibres of the vestibular branch of the vestibulocochlear nerve. They enter the cerebellum with the ascending branch of the vestibular nerve, and pass through the superior vestibular nucleus and the juxtarestiform body. They terminate, mainly ipsilaterally, in the granular layer of the nodule, caudal part of the uvula, ventral part of the anterior lobe and bottom of the deep fissures of the vermis (Fig. 20.9A). Secondary vestibulocerebellar mossy fibres arise from the superior vestibular nucleus and the caudal portions of the medial and inferior vestibular nuclei. They terminate bilaterally not only in the same regions that receive primary vestibulocerebellar fibres but also in the flocculus, which lacks a primary vestibulocerebellar projection (Fig. 20.9B). Some of the mossy fibres from the medial and inferior vestibular nuclei are cholinergic.

**Reticulocerebellar fibres**

The lateral reticular nucleus of the medulla oblongata, and the paramedian reticular and tegmental reticular nuclei of the pons, give rise to mossy fibres. The latter nuclei also supply major collateral projections to the cerebellar nuclei. Spinoreticular fibres terminate in a somatotopical pattern within the entire lateral reticular nucleus, where they overlap with collaterals from the rubrospinal and lateral vestibulospinal tracts and a projection from the cerebral cortex.

The lateral reticular nucleus projects bilaterally to the vermis and hemispheres of the cerebellum. The projection from the dorsal part of the nucleus, which receives collaterals from the rubrospinal tract in addition to spinal afferents, is centred on the ipsilateral hemisphere. The ventral part of the nucleus, which receives a strong projection from the spinal cord and a collateral projection from the lateral vestibulospinal tract, projects bilaterally, mainly to the vermis. The lateral reticular nucleus provides a strong projection to the superior fastigial nucleus, the emboliform nucleus and the medial pole of the globose nucleus.

The paramedian reticular nucleus consists of cell groups at the lateral border of the medial longitudinal fasciculus. It receives fibres from the vestibular nuclei and the interstitiospinal and tectospinal tracts (which descend in the medial longitudinal fasciculus), and from the spinal cord and the cerebral
cortex. It projects to the entire cerebellum.

The tegmental reticular nucleus of the pons is located next to the midline in the caudal half of the tegmentum. It receives afferent connections from the cerebral cortex, tectum, nucleus of the optic tract and cerebellar nuclei via the crossed descending branch of the superior cerebellar peduncle. Efferents from the tegmental reticular nucleus reach the cerebellum through the middle cerebellar peduncle. Some terminate superficially in the cortex of the anterior lobe, but many more end in the simple lobule, folium, tuber, vermis and adjoining flocculus. Additional efferents terminate in the caudal fastigial nucleus, dentate nucleus and lateral parts of the globose nucleus.

**Pontocerebellar fibres**

The cerebral cortex is the largest single source of fibres that project to the pontine nuclei. Fibres from the pontine nuclei access the cerebellum via the middle cerebellar peduncle, which is the largest afferent system of the human cerebellum. Many corticopontine fibres are collaterals of axons that project to other targets in the brain or spinal cord, e.g. it is likely that all corticospinal fibres give off collaterals to the pontine nuclei. Although corticopontine axons arise from lamina V pyramidal cells, the projection from different areas of the cerebral cortex is highly uneven. The areas of cerebral cortex that project to the pontine nuclei are those that are particularly involved in the control of movement. For example, in the case of visual areas, the input arises from extrastriate visual areas in the parietal lobe whose cells are responsive to movement, and function as important links in the visual guidance of movement. Dorsal pontine nuclei receive collateral branches from corticotectal fibres that project to the superior and inferior colliculi from the parietal, temporal and frontal areas of the cerebral cortex, and from tectopontine relays. The onward pontocerebellar projections are to the simple lobule and to the folium and tuber of the vermis.

Fibres of the pontine reticular nuclei are distributed bilaterally, with ipsilateral predominance, to all lobules of the cerebellum other than the lingula and nodule.

More than 90% of fibres in the middle cerebellar peduncle belong to the cortico-ponto-cerebellar pathway. Corticopontine fibres travel in the cerebral peduncle. Fibres from the frontal lobe occupy the medial part of the peduncle, and fibres from the parietal, occipital and temporal lobes occupy the lateral part. They synapse on some 20 million neurones in corresponding regions of the basilar pons. The onward pontocerebellar mossy fibre projection is predominantly to the lateral regions of the posterior and anterior lobes (Fig. 20.4) but collaterals are given off to the dentate nucleus.
EFFERENT CONNECTIONS OF THE CEREBELLUM

The output of the cerebellum consists of the inhibitory projections of the Purkinje cells to the cerebellar and vestibular nuclei, and the efferent connections of the cerebellar nuclei to motor centres in the brain stem and, through the thalamus, the motor cortex. Their effects on movement are always indirect, because there are no direct projections from the cerebellar nuclei to motor neurones. Disynaptic connections of the Purkinje cells in the anterior vermis and vestibulocerebellum with motor neurones controlling oculogyric and proximal limb muscles are mediated by the vestibular nuclei. The vermis also influences these motor neurones bilaterally through multisynaptic pathways that involve the fastigial and vestibular nuclei and the reticular formation (Fig. 20.12). The vermis cannot be considered as a single module. Each half of the vermis is composed of several modules (each made up of a longitudinal Purkinje cell zone and a target nucleus) and their supporting climbing fibre afferent projections.
Fig. 20.12  Efferent connections of the cerebellar vermis. Connections of the A zones of the vermis and flocculonodular lobe with the fastigial nucleus are indicated, also those of the B zone with the lateral vestibular nucleus. Some vestibular efferents ascend bilaterally to the ocular motor nuclei and thalamus, others descend to the spinal cord. Motor nuclei of the 3rd, 4th and 6th cranial nerves: III, IV, VI.

Each cerebellar hemisphere influences movements of the ipsilateral extremities by way of projections to the dentate and interposed (emboliform and globose) nuclei, which in turn project to the contralateral red nucleus, thalamus and motor cortex (Fig. 20.13).
Corticonuclear and corticovestibular fibres

Purkinje cells of each hemivermis project to the ipsilateral fastigial and vestibular nuclei. Purkinje cells of the hemisphere project to the interposed and dentate nuclei. Although the cerebellar cortex is organized in strips of Purkinje cell zones, which project to different cerebellar and vestibular nuclei, the borders between these strips are not apparent in the structure of the cortex when it is examined histologically using conventional staining methods. The vermis of the anterior lobe and simple lobule consist of two parallel strips, A and B, of Purkinje cells (Figs 20.10, 20.12). The medial strip (A zone) projects to the rostral pole of the fastigial nucleus, and the lateral strip (B zone) projects to the lateral vestibular nucleus. The B zone does not continue beyond the simple lobule. The cortex of the entire caudal vermis, which projects to the fastigial nucleus, is included in the A zone. The folium

Fig. 20.13  Efferent connections of the cerebellar hemisphere. Purkinje cell zones and their target nuclei are indicated with the same colours. Efferent fibres from the motor cortex and from the very small magnocellular red nucleus recross and descend to the upper part of the spinal cord.
and tuber, which represent a region of the cerebellum that receives a visual input and which are involved in the accurate calibration of saccades, project to the caudal pole of the fastigial nucleus. The pyramis, uvula and nodule can be subdivided into several Purkinje cell zones. However, the significance of their connections with the cerebellar and vestibular nuclei is not well understood. Corticovestibular projections to the superior, medial and inferior vestibular nuclei, but not to the lateral nucleus, take their origin from the nodule and the adjacent region of the uvula.

The intermediate region consists of two strips of Purkinje cells (C1 and C3 zones), which project to the emboliform (anterior interposed) nucleus. They flank a single zone (C2) that projects to the globose (posterior interposed) nucleus (Figs 20.10, 20.13). The rest of the hemisphere projects to the dentate nucleus. There are indications for a subdivision of the hemisphere into two zones that project to the caudolateral and rostromedial parts of the dentate nucleus, respectively. The neurones of the caudolateral dentate are generally smaller than those of the rostromedial portion and the convolutions are broader. The efferent connections of the flocculus are mainly with the superior, medial and inferior vestibular nuclei and resemble those from the nodule and uvula.

**Cerebellovestibular and cerebelloreticular fibres**

**Efferent connections of the fastigial nucleus**

The fastigial nucleus is connected bilaterally with the vestibular nuclei and the medullary and pontine reticular formation (Fig. 20.12). Smaller crossed connections either ascend to the midbrain and diencephalon or descend into the spinal cord. Small GABAergic neurones give rise to fastigio-olivary fibres, which terminate in the medial accessory olive. The uncinate fasciculus is the major efferent pathway of the fastigial nucleus. Its fibres cross in the rostral part of the cerebellar white matter, and pass dorsal to the superior cerebellar peduncle, to enter the vestibular nuclei from their lateral side. Uncrossed fibres enter the vestibular nuclei through the juxtarestiform body. The distribution of the fastigial projection is bilateral, but with a contralateral preponderance. Crossed and uncrossed projections end in the medial and inferior vestibular nuclei, and also traverse these nuclei to terminate in the medial reticular formation. Some crossed fibres can be traced caudally into the spinal cord. A small fascicle of crossed fibres from the fastigial nucleus ascends along the superior cerebellar peduncle and is distributed bilaterally to the dorsal tegmentum, central grey matter and deep layers of the superior colliculus and the nuclei of the posterior commissure. Fibres terminate bilaterally in the ventrolateral nucleus and the intralaminar nuclei of the thalamus.

**Cerebellovestibular connections**

The relationship between the cerebellum and the vestibular nuclei is complex (Figs 20.9, 20.12). In addition to the vestibulocerebellum (nodule, adjacent folia of the uvula and flocculus), the main vermis and the fastigial nucleus also project to the vestibular nuclei.

The vestibulocerebellum projects to the superior, medial and inferior vestibular...
nuclei. Neurones of these nuclei, which receive an input from the vestibular nerve and project to the nuclei controlling eye movements (vestibulo-ocular relay cells), are among the main targets of the Purkinje cells of the nodule and flocculus. Through these connections with vestibulo-ocular relay neurones, the flocculus is involved in the long-term adaptation of compensatory eye movements, the generation of smooth eye movements used to pursue an object, and the suppression of the vestibulo-ocular reflex during smooth pursuit. The function of the nodule in the control of eye movement is less well understood.

The vestibular nuclei are the main source of mossy fibre afferents to the nodule; their projection to the flocculus is relatively minor. Most mossy fibres which terminate in the flocculus arise from the reticular formation and relay optokinetic and visual information.

The lateral vestibular nucleus, which lacks an input from the labyrinth and receives Purkinje cell axons from the B zone of the anterior vermis, can be regarded as a displaced cerebellar nucleus. It gives rise to the lateral vestibulospinal tract, which descends to all levels of the spinal cord. It is avoided by the efferent pathways from the fastigial nucleus, which terminate more ventrally on large neurones in the magnocellular part of the medial vestibular nucleus and in the medial reticular formation. The medial and inferior vestibular nuclei receive a major input from the vestibular nerve and give rise to bilaterally ascending and descending tracts that course in the medial longitudinal fasciculus. The ascending tract is composed predominantly of the axons of vestibulo-ocular relay cells. The descending fibres form the medial vestibulospinal tract, which is particularly involved in head righting reflexes when the trunk is tilted.

Fastigial fibres, which terminate in the reticular formation, stimulate the bilaterally descending medullary reticulospinal tracts. The A zone of the vermis exerts a bilateral influence on ventromedially located spinal interneurones and motor neurones that innervate axial, truncal and proximal limb muscles. Some fibres of the uncinate tract descend as far as the cervical cord, where they terminate on the same motor neurones. The B zone exerts an influence on ipsilateral interneurones and motor neurones of the same system through its projection to the lateral vestibular nucleus and the lateral vestibulospinal tract.

The projections of the fastigial nucleus to the thalamus are relatively minor. They are bilateral, because the crossed ascending fibres of the uncinate fasciculus subsequently recross. Their targets include parts of the ventrolateral nucleus and the intralaminar, centrolateral and parafascicular nuclei. Fibres that terminate in the ventrolateral nucleus lie medial to the terminations of fibres from the dentate and interposed nuclei. This region of the ventrolateral nucleus projects to the motor cortex but also sends collaterals to the medullary reticular formation, which influences ventromedial interneurones and motor neurones in lumbar and sacral segments of the spinal cord via the medullary reticulospinal tracts.

The caudal region of the fastigial nucleus receives Purkinje cell axons from the folium and tuber, an area of the vermis that receives visual inputs. It projects to the contralateral horizontal gaze centre (paramedian pontine reticular formation, PPRF), and the vertical gaze centre (rostral interstitial nucleus of the medial
longitudinal fasciculus, riMLF), and bilaterally, to deep layers of the superior colliculus. These projections probably mediate the adaptation of saccades by the vermal visual area.

The cerebellum influences visceromotor systems via the projections of the fastigial nucleus to the parasolitary nucleus (a region bordering the viscerosensory nuclei of the solitary tract), the dorsal motor nucleus of the vagus, the central grey matter, the serotoninergic raphe nuclei of the pons and medulla, and the noradrenergic locus coeruleus.

Other pathways from the cerebellar nuclei terminate on precerebellar relay nuclei that give rise to mossy or climbing fibres. Recurrent circuits involving the fastigial nucleus include the nucleus reticularis tegmenti pontis and a projection from the fastigial nucleus to the medial accessory olive. Nucleo-olivary projections arise from all the cerebellar nuclei, are crossed, and contain GABA as a neurotransmitter. The connections of the fastigial nucleus with the reticular nuclei are excitatory.

Cerebellar nuclei also project to the contralateral interstitial nucleus of Darkschewitsch, which lies at the boundary between the midbrain and diencephalon. This nucleus projects to the medial accessory olive via the central tegmental tract. The fastigial nucleus controls the climbing fibre output of the medial accessory olive, both via its nucleo-olivary projection and by its connection to the nucleus of Darkschewitsch.

Cerebellorubral and cerebellothalamic fibres

The axons of neurones in the dentate and interposed nuclei leave the cerebellum in the superior cerebellar peduncle. The superior peduncles, including their nucleo-olivary component, decussate in the caudal midbrain (Fig. 20.13) and each then gives off a small descending branch carrying fibres that terminate in the medial reticular formation of the pons and medulla and the pontine tegmental reticular nucleus. The nucleo-olivary fibres join this descending branch and terminate in the inferior olive in a strictly ordered manner. The ascending branch is distributed to the midbrain and diencephalon, mainly to the red nucleus and thalamus. The emboliform (anterior interposed) nucleus projects to the magnocellular part of the red nucleus. In humans this projection is very small and the target neurones give rise to a relatively trivial rubrospinal tract, which crosses in the caudal midbrain and terminates on lateral medullary interneurones and a small number of motor neurones in the upper cervical spinal cord.

The emboliform (anterior interposed) nucleus projects to lateral parts of the ventrolateral nucleus of the thalamus, which are connected with elements of the motor cortex projecting to axial and proximal limb muscles, and to the reticular formation of the pons and medulla. It also projects to the pontine tegmental reticular nucleus and to basal pontine nuclei, both of which give rise to mossy fibres. Its nucleo-olivary efferents terminate in the rostral half of the dorsal accessory olive.

The projections of the globose (posterior interposed) nucleus are very similar to
those of the fastigial nucleus. The two nuclei share projections to the cord, the superior colliculus, the central grey matter and the raphe nuclei. Nucleo-olivary projections from the globose nucleus and the recurrent globose nucleus–interstitial nucleus–inferior olivary nucleus pathway converge upon the rostral half of the medial accessory olive. The thalamic projections overlap those from the fastigial and emboliform nuclei.

The dentate nucleus projects to the contralateral parvicellular red nucleus and the thalamus. The central tegmental tract takes its origin from the parvocellular red nucleus and terminates on the principal nucleus of the olive. The thalamic projection to the ventrolateral nucleus overlaps those of the other cerebellar nuclei. The inferior and lateral parts of the dentate nucleus project into the most medial region of the ventrolateral nucleus, which in turn projects to the premotor area of the frontal lobe.

The thalamus receives a massive input from other major motor systems, in addition to the input it receives from the cerebellum. In particular, the output of the basal ganglia is relayed to the thalamus by a projection from the globus pallidus (Ch. 22). Available evidence suggests that these two great subcortical motor systems terminate on different regions in the ventral thalamus and project to different targets in the motor and premotor cortex.
CEREBELLAR FUNCTIONS

The vermis of the cerebellum is involved in taking anticipatory action in order to maintain an upright posture when objects are picked up. For example, when a book is taken down from a shelf, the first muscle groups to be activated are not the flexors of shoulder, elbow or fingers, but the plantar flexors of the ankle. Contraction of the ankle flexors causes the forefeet to push the lower limbs and trunk backwards at the moment the hand grasps the book. Once the lift gets under way, the erector spinae muscles correct for the combined weights of the book and the reaching arm, in order to prevent forward sway of the head and trunk. Labyrinthine receptors simultaneously inform the cerebellum of any forward movement of the head, and appropriate antigravity thrust is exerted via one or both lateral vestibulospinal tracts.

The posterolateral region of the cerebellum has a role in postural fixation to prevent oscillation of distal limb parts caused by the viscoelastic properties of the muscles in response to sudden movements. If a volunteer is instructed to exert rapid wrist extension and to maintain the extended posture for two seconds, electromyographic records taken from the prime movers and antagonists reveal that the antagonists begin to contract prior to completion of the movement, and that they continue to contract and relax several times in alternating fashion with the prime movers, although with much less force, during the measured fixation period.

The cerebellum has a role in motor learning. Experimental studies have shown that when a novel motor skill is being learned, the olivocerebellar climbing fibre system becomes active when errors are made. The inferior olivary complex appears to be involved in correction, based on receipt of a copy of the intended movement from collateral branches of the corticospinal tract. Cerebellar output via the superior cerebellar peduncle is also copied on to the parvicellular red nucleus and projected from there to the inferior olive, where it can be compared with the original. Short bursts of climbing fibre activity depress the Purkinje cells responsible for producing the errors.

Many motor skills require precise timing, which involves an extreme degree of cooperation between prime movers and their antagonists. For example, reading a printed page requires that the scanning eyes snap back to the beginning of a line, time after time: even small errors may result in dyslexia, where slight incoordination of eye movements may cause the letters of a word to appear jumbled. Clinical testing of timing can be performed easily by checking the ability to perform rhythmic movements such as repetitive pronation/supination (Fig. 20.14).

CEREBELLAR LESIONS

Midline cerebellar lesions, e.g. tumours such as medulloblastoma and secondary carcinoma, lead to abnormalities of posture, so that the patient cannot sit or stand, without toppling, usually backwards.

Unilateral lesions in the cerebellar hemispheres, e.g. stroke, produce ipsilateral symptoms and signs. Inco-ordination of eye movements leads to nystagmus, which is most marked when gaze is directed to the side of the lesion. Incoordination of the ipsilateral upper limb is manifested in the finger-nose test. The movements are inaccurate (dysmetria); the limb oscillates to and fro, the amplitude being greater as the target is reached (intention tremor); there is a breakdown of smooth co-operation between muscles controlling the joints of the upper limb (asynergia); alternating hand movements are clumsy (dysdiadochokinesia). When the arm is outstretched, there is a tendency for the limb to hyper-pronate and rise, and when pressure is applied to the extended arm and then released, there is a marked rebound of the limb. Unilateral incoordination of the lower limb is apparent because heel/shin testing is inaccurate.

Bilateral lesions of the cerebellar hemisphere lead to nystagmus and a form of dysarthria in which the syllables are extended and prosody is lost (scanning speech). The gait is wide based, reeling, and incoordinate (ataxia): the ataxia is not made significantly worse on eye closure (negative Romberg's sign). Bilateral lesions can be acute, as in the encephalitis that follows chicken pox, or chronic, as in alcohol abuse, and the inherited spinocerebellar ataxias. The co-occurrence of nystagmus, scanning speech and intention tremor were held by the 19th century neurologist Charcot to be pathognomonic of multiple sclerosis.

It has been speculated that cerebellar lesions may lead to disorders of higher cortical function and changes in affect, but this has not been substantiated.
REFERENCES

One of several studies using fMRI which have indicated that the right posterolateral cerebellum is involved during word retrieval and syntax generation.

CHAPTER 21 – Diencephalon

The diencephalon is part of the prosencephalon (forebrain), which develops from the foremost primary cerebral vesicle and differentiates into a caudal diencephalon and rostral telencephalon. The cerebral hemispheres develop from the sides of the telencephalon, each containing a lateral ventricle. The sites of evagination become the interventricular foramina, through which the two lateral ventricles and midline third ventricle communicate. The diencephalon corresponds largely to the structures that develop lateral to the third ventricle. The lateral walls of the diencephalon form the epithalamus most superiorly, the thalamus centrally and the subthalamus and hypothalamus most inferiorly.

**THALAMUS**

The thalamus is an ovoid nuclear mass, about 4 cm long, which borders the dorsal part of the third ventricle (Figs 21.1, 21.2). The narrow anterior pole lies close to the midline, and forms the posterior boundary of the interventricular foramen. Posteriorly, an expansion, the pulvinar, extends beyond the third ventricle to overhang the superior colliculus (see Fig. 19.3). The brachium of the superior colliculus (superior quadrigeminal brachium) separates the pulvinar above from the medial geniculate body below. A small oval elevation, the lateral geniculate body, lies lateral to the medial geniculate.

(By courtesy of Professor Alan Jackson, Wolfson Molecular Imaging Centre, The University of Manchester, Manchester, UK.)
The superior (dorsal) surface of the thalamus (see Fig. 19.3) is covered by a thin layer of white matter, the stratum zonale. It extends laterally from the line of reflection of the ependyma (taenia thalami), and forms the roof of the third ventricle. This curved surface is separated from the overlying body of the fornix by the choroid fissure with the tela choroidea within it. More laterally, it forms part of the floor of the lateral ventricle. The lateral border of the superior surface of the thalamus is marked by the stria terminalis and overlying thalamostriate vein, which separate the thalamus from the body of the caudate nucleus. Laterally, a slender sheet of white matter, the external medullary lamina, separates the main body of the thalamus from the reticular nucleus. Lateral to this, the thick posterior limb of the internal capsule lies between the thalamus and the lentiform complex.

The medial surface of the thalamus is the superior (dorsal) part of the lateral wall of the third ventricle. It is usually connected to the contralateral thalamus by an interthalamic adhesion behind the interventricular foramina (see Fig. 16.7). The boundary with the hypothalamus is marked by an indistinct hypothalamic sulcus, which curves from the upper end of the cerebral aqueduct to the interventricular foramen. The thalamus is continuous with the midbrain tegmentum, the subthalamus and the hypothalamus.

Internally, the greater part of the thalamus is divided into anterior, medial and lateral nuclear groups by a vertical Y-shaped sheet of white matter, the internal medullary lamina (Figs 21.3, 21.4). In addition, intralaminar nuclei lie embedded within the internal medullary lamina and midline nuclei abut the lateral walls of the third ventricle. The reticular nucleus forms a shell-like lateral covering to the main nuclear mass, separated from it by an external medullary lamina of nerve fibres.
Fig. 21.3 The main nuclear aggregations of cell bodies in the diencephalon (coronal sections). A, At the level of the mammillary bodies. B, At the level of the tuber cinereum. Note the variations in cell size, shape and packing density, which characterize the nuclear masses of the thalamus, subthalamus and hypothalamus at these levels.
Fig. 21.4 The main nuclear masses of the thalamus (viewed from the lateral aspect in the lower illustration) colour coded to indicate the areas of cerebral neocortex with which they are interconnected. The lack of colour in the centromedial, intralaminar and reticular nuclei of the thalamus does not related to the colour code. The reticular nucleus lies lateral to the main mass of the thalamus. Only the anterior pole of the reticular nucleus is shown, its posterior extent being depicted by the heavy interrupted line.

In general, thalamic nuclei both project to and receive fibres from the cerebral cortex (Fig. 21.4). The whole cerebral cortex, including neocortex, paleocortex of the piriform lobe and archicortex of the hippocampal formation, is reciprocally connected with the thalamus. The thalamus is the major route by which subcortical neuronal activity influences the cerebral cortex, and the greatest input to most thalamic nuclei comes from the cerebral cortex.

The projection to the thalamus from the cortex is precisely reciprocal; each cortical area projects in a topographically organized manner to all sites in the thalamus from which it receives an input. Thalamocortical fibres terminate predominantly in layer IV of the cortex. Corticothalamic fibres which reciprocate ‘specific’ thalamocortical pathways arise from modified pyramidal cells of layer VI, whereas those reciprocating ‘non-specific’ inputs arise from typical pyramidal cells of layer V, and may in part be axon collaterals of other cortico-subcortical pathways.

It is customary to consider thalamic nuclei as either ‘specific’ nuclei, which mediate finely-organized and precisely-transmitted sensory information to discrete cortical sensory areas, or as ‘non-specific’ nuclei, which are part of a general arousal system. The specific nuclei are further subdivided into relay nuclei and association nuclei. However, many nuclei classified as specific may also send non-specific projections to widespread cortical areas. Similarly, the division of thalamic nuclei into relay and association groups rests upon the assumption that relay nuclei receive a major subcortical pathway, whereas association nuclei receive their principal non-cortical input from other thalamic nuclei. There is little evidence of significant intrathalamic connectivity, but increasing indications of non-cortical afferent pathways linked to so-
called association nuclei: the extensive connectivity between the reticular nucleus and other thalamic nuclei is a notable exception.

**ANTERIOR THALAMIC NUCLEI**

The anterior group of nuclei are enclosed between the arms of the Y-shaped internal medullary lamina, and underlie the anterior thalamic tubercle (see Figs 19.3, 21.4). Three subdivisions are recognized: the largest is the anteroventral nucleus, the others being the anteromedial and anterodorsal nuclei.

The anterior nuclei are the principal recipients of the mammillo-thalamic tract, which arises from the mammillary nuclei of the hypothalamus. The mammillary nuclei receive fibres from the hippocampal formation via the fornix. The medial mammillary nucleus projects to the ipsilateral anteroventral and anteromedial thalamic nuclei, and the lateral mammillary nucleus projects bilaterally to the anterodorsal nuclei. The nuclei of the anterior group also receive a prominent cholinergic input from the basal forebrain and the brain stem.

The cortical targets of efferent fibres from the anterior nuclei of the thalamus lie largely on the medial surface of the hemisphere. They include the anterior limbic area (in front of and inferior to the corpus callosum), the cingulate gyrus, and the parahippocampal gyrus (including the medial entorhinal cortex and the pre- and para-subiculum). These thalamocortical pathways are reciprocal. There also appear to be minor connections between the anterior nuclei and the dorsolateral prefrontal and posterior areas of neocortex. The anterior thalamic nuclei are believed to be involved in the regulation of alertness and attention and in the acquisition of memory.
MEDIAL THALAMIC NUCLEI

The single component of this thalamic region is the mediodorsal or dorsomedial nucleus, which is particularly large in man. Laterally, it is limited by the internal medullary lamina and intralaminar nuclei. Medially, it abuts the midline parataenial and reuniens (medioventral) nuclei. It is divided into anteromedial magnocellular, and postero-lateral parvocellular, parts.

The smaller magnocellular division receives olfactory input from the piriform and adjacent cortex, the ventral pallidum, and the amygdala. The mediobasal amygdaloid nucleus projects to the dorsal part of the anteromedial magnocellular nucleus, and the lateral nuclei project to the more central and anteroventral regions. The anteromedial magnocellular nucleus projects to the anterior and medial prefrontal cortex, notably to the lateral posterior and central posterior olfactory areas on the orbital surface of the frontal lobe. In addition, fibres pass to the ventromedial cingulate cortex and some to the inferior parietal cortex and anterior insula. These cortical connections are reciprocal.

The larger, posterolateral parvocellular division connects reciprocally with the dorsolateral and dorsomedial prefrontal cortex, the anterior cingulate gyrus and the supplementary motor area. In addition, efferent fibres pass to the posterior parietal cortex.

The mediodorsal nucleus appears to be involved in a wide variety of higher functions. Damage may lead to a decrease in anxiety, tension, aggression or obsessive thinking. There may also be transient amnesia, with confusion developing particularly over the passage of time. Much of the neuropsychology of medial nuclear damage reflects defects in functions similar to those performed by the prefrontal cortex, with which it is closely linked. The effects of ablation of the mediodorsal nuclei parallel, in part, the results of prefrontal lobotomy.
LATERAL THALAMIC NUCLEI

The lateral nuclear complex, lying lateral to the internal medullary lamina, is the largest division of the thalamus. It is divided into dorsal and ventral tiers of nuclei. The lateral dorsal nucleus, lateral posterior nucleus and the pulvinar all lie dorsally. The lateral and medial geniculate nuclei lie inferior to the pulvinar near the posterior pole of the thalamus. The ventral tier nuclei are the ventral anterior, ventral lateral and ventral posterior nuclei.

Ventral anterior nucleus

The ventral anterior (VA) nuclear complex lies at the anterior pole of the ventral nuclear group. It is limited anteriorly by the reticular nucleus, posteriorly by the ventral lateral nucleus, and lies between the external and internal medullary laminae. It consists of a principal part (VApc) and a magnocellular part (VAmc). The subcortical connections to this region are largely ipsilateral from the internal segment of the globus pallidus and the pars reticulata of the substantia nigra. The terminal fields from these origins do not overlap. Fibres from the globus pallidus end in VApc. The substantia nigra projects to VAmc. Corticothalamic fibres from premotor cortex (area 6) terminate in VApc and fibres from the frontal eye field (area 8) terminate in VAmc. VA thalamus does not appear to receive fibres directly from the motor cortex. The efferent projections from VA are incompletely known. Some pass to intralaminar thalamic nuclei and others project to widespread regions of the frontal lobe and to the anterior parietal cortex. Their functions are unclear. The VA thalamus appears to play a central role in the transmission of the cortical 'recruiting response', a phenomenon in which stimulation of the thalamus can initiate long-lasting, high voltage repetitive negative electrical waves over much of the cerebral cortex.

Ventral lateral nucleus

The ventral lateral (VL) nucleus consists of two major divisions with distinctly different connections and functions. The anterior division, or pars oralis (VLo), receives topographically organized fibres from the internal segment of the ipsilateral globus pallidus. The posterior division, or pars caudalis (VLc), receives topographically organized fibres from the contralateral deep cerebellar nuclei. Additional subcortical projections have been reported from the spinothalamic tract and the vestibular nuclei. Numerous cortical afferents to both VLo and VLc originate from precentral motor cortical areas, including both area 4 and area 6.

The VLo nucleus sends efferent fibres to the supplementary motor cortex on the medial surface of the hemisphere and to the lateral premotor cortex. The VLc nucleus projects efferent fibres to the primary motor cortex where they end in a topographically arranged fashion. The head region of area 4 receives fibres from the medial part of VLc, and the leg region receives fibres from lateral VLc.

Approximately 70% of VL neurones are large relay neurones, and the other 30% are local circuit interneurones. Responses can be recorded in VL thalamus during both passive and active movement of the contralateral body. The topography of its connections, and recordings made within the nucleus, suggest that VLc contains a body representation comparable to that in the ventral posterior nucleus. In patients with tremor, clusters of VL neurones fire in bursts that are synchronous with peripheral
tremor: these cells have been designated as ‘tremor cells’. Stereotaxic surgery of the ventral lateral nucleus is sometimes used in the treatment of essential tremor. In the past, thalamotomy was used extensively for the treatment of Parkinson's disease. The internal segment of the globus pallidus and the subthalamic nucleus are now the preferred neurosurgical targets for Parkinson's disease (see Ch. 22).

**Ventral posterior nucleus**

The ventral posterior (VP) nucleus is the principal thalamic relay for the somatosensory pathways. It is thought to consist of two major divisions, the ventral posterolateral (VPL) and ventral posteromedial (VPM) nuclei. The VPL nucleus receives the medial lemniscal and spinothalamic pathways, and the VPM nucleus receives the trigeminothalamic pathway. Connections from the vestibular nuclei and lemniscal fibres terminate along the ventral surface of the VP nucleus.

There is a well-ordered topographic representation of the body in the ventral posterior nucleus. The VPL is organized so that sacral segments are represented laterally and cervical segments medially. The latter abut the face area of representation (trigeminal territory) in VPM. Taste fibres synapse most anteriorly and ventromedially within the ventral posterolateral nucleus.

At a more detailed level, single body regions are represented as curved lamellae of neurones, parallel to the lateral border of the ventral posterior nucleus, such that there is a continuous overlapping progression of adjacent receptive fields from dorsolateral to ventromedial. Considerably less change in location of receptive field on the body is seen when passing anteroposteriorly through the nucleus. While not precisely dermatomal in nature, these curvilinear lamellae of cells probably derive from afferents related to a few adjacent spinal segments. There is considerable distortion of the body map within the nucleus, reflecting the differences in the density of peripheral innervation which occur in different body regions, e.g. many more neurones respond to stimulation of the hand than of the trunk. Within a single lamella, neurones in the anterodorsal part of the nucleus respond to deep stimuli, including movement of joints, tendon stretch, and manipulation of muscles. Most ventrally, neurones once again respond to deep stimuli, particularly tapping. Intervening cells within a single lamella respond only to cutaneous stimuli. This organization has been confirmed by recordings made in the human ventral posterior nucleus.

Single lemniscal axons have an extended anteroposterior terminal zone within the nucleus. Rods of cells running the length of the anteroposterior, dorsoventrally oriented, lamellae respond with closely similar receptive field properties and locations, derived from a small bundle of lemniscal afferents. It appears, therefore, that each lamella contains the complete representation of a single body part, e.g. a finger. Lamellae consist of multiple narrow rods of neurones, oriented anteroposteriorly, each of which receives input from the same small region of the body that is represented within the lamella, and from the same type of receptors. These thalamic ‘rods’ form the basis for both the place- and modality-specific input to columns of cells in the somatic sensory cortex. Spinothalamic tract afferents to the ventral posterolateral nucleus terminate throughout the nucleus. The neurones from which these axons originate appear to be mainly of the ‘wide dynamic range’ class, responding to both low threshold mechanoreceptors and high threshold nociceptors; a smaller proportion of neurones respond exclusively to high-threshold nociceptors. Some neurones
respond to temperature changes. There is evidence that spinothalamic tract neurones carrying nociceptive and thermal information terminate in a distinct nuclear area, identified as the posterior part of the ventral medial nucleus (VMpo).

The VP nucleus projects to the primary somatic sensory cortex (SI) of the postcentral gyrus and to the second somatic sensory area (SII) in the parietal operculum. VMpo projects to the insular cortex. Within the primary sensory cortex, the central cutaneous core of the VP nucleus projects solely to area 3b; dorsal and ventral to this, a narrow band of cells projects to both 3b and area 1. The most dorsal and ventral deep stimulus receptive cells project to areas 3a and 2. The whole nucleus projects to the second somatic sensory area.

**Medial geniculate nucleus**

The medial geniculate nucleus, which is a part of the auditory pathway (see Ch. 37), is located within the medial geniculate body, a rounded elevation situated posteriorly on the ventrolateral surface of the thalamus, and separated from the pulvinar by the superior quadrigeminal brachium. It receives fibres travelling in the inferior quadrigeminal brachium. Three major subnuclei, medial, ventral and dorsal, are recognized within it. The inferior brachium separates the medial (magnocellular) nucleus, which consists of sparse, deeply staining neurones, from the lateral nucleus, which is made up of medium-sized, densely packed and darkly staining cells. The dorsal nucleus overlies the ventral nucleus and expands posteriorly; it is, therefore, sometimes known as the posterior nucleus of the medial geniculate. It contains small- to medium-sized, pale-staining cells, which are less densely packed than those of the lateral nucleus. The ventral nucleus receives fibres from the central nucleus of the ipsilateral inferior colliculus via the inferior quadrigeminal brachium and also from the contralateral inferior colliculus. The nucleus contains a complete tonotopic representation. Low-pitched sounds are represented laterally, and progressively higher-pitched sounds are encountered as the nucleus is traversed from lateral to medial. The dorsal nucleus receives afferents from the pericentral nucleus of the inferior colliculus and from other brain stem nuclei of the auditory pathway. A tonotopic representation has not been described in this subdivision and cells within the dorsal nucleus respond to a broad range of frequencies. The magnocellular medial nucleus receives fibres from the inferior colliculus and from the deep layers of the superior colliculus. Neurones within the magnocellular subdivision may respond to modalities other than sound. However, many cells respond to auditory stimuli, usually to a wider range of frequencies than neurones in the ventral nucleus. Many units show evidence of binaural interaction, with the leading effect arising from stimuli in the contralateral cochlea. The ventral nucleus projects primarily to the primary auditory cortex. The dorsal nucleus projects to auditory areas surrounding the primary auditory cortex. The magnocellular division projects diffusely to auditory areas of the cortex and to adjacent insular and opercular fields.

**Lateral geniculate nucleus**

The lateral geniculate body, which is part of the visual pathway (see Ch. 40), is a small, ovoid, ventral projection from the posterior thalamus (Fig. 21.5). The superior quadrigeminal brachium enters the posteromedial part of the lateral geniculate body dorsally, lying between the medial geniculate body and the pulvinar.
Fig. 21.5 Coronal section through the brain showing the lateral geniculate nucleus.
The lateral geniculate nucleus is an inverted, somewhat flattened, U-shaped nucleus and is laminated. Its internal organization is usually described on the basis of six laminae, although seven or eight may be present. The laminae are numbered 1 to 6, from the innermost ventral to the outermost dorsal (Fig. 21.6). Laminae 1 and 2 consist of large cells, the magnocellular layers, whereas layers 4 to 6 have smaller neurones, the parvocellular laminae. The apparent gaps between laminae are called the interlaminar zones. Most ventrally an additional superficial, or S, lamina is recognized.

Fig. 21.6 Coronal sections through the lateral geniculate nucleus illustrating the laminar arrangement of neurones (A) near its central region and (B) near its posterior pole.
The lateral geniculate nucleus receives a major afferent input from the retina. The contralateral nasal hemiretina projects to laminae 1, 4 and 6, whereas the ipsilateral temporal hemiretina projects to laminae 2, 3 and 5. The parvocellular laminae receive axons predominantly of X-type retinal ganglion cells, i.e. more slowly conducting cells with sustained responses to visual stimuli. The faster conducting, rapidly adapting Y-type retinal ganglion cells project mainly to the magnocellular laminae 1 and 2, and give off axonal branches to the superior colliculus. A third type of retinal ganglion cell, the W cells, which have large receptive fields and slow responses, project to both the superior colliculus and the lateral geniculate nucleus, where they terminate particularly in the interlaminar zones and in the S lamina.

The lateral geniculate nucleus is organized in a visuotopic manner and it contains a precise map of the contralateral visual field. The vertical meridian is represented posteriorly, the peripheral anteriorly, the upper field laterally, and the lower field medially. Similar precise, point-to-point, representation is also found in the projection of the lateral geniculate nucleus to the visual cortex. Radially arranged inverted pyramids of neurones in all laminae respond to a single, small area of the contralateral visual field and project to a circumscribed area of cortex. The termination of geniculocortical axons in the visual cortex is considered in detail elsewhere (see Ch. 23).

Aside from retinal afferents, the lateral geniculate nucleus receives a major corticothalamic projection, the axons of which ramify densely in the interlaminar zones. The major part of this projection arises from the primary visual cortex, Brodmann's area 17, but smaller projections from extrastriate visual areas pass to the magnocellular and S laminae. Other afferents include: fibres from the superficial layer of the superior colliculus (which terminate in the interlaminar zone between laminae 1 and 2, 2 and 3, and around lamina S); noradrenergic fibres from the locus coeruleus; serotoninergic afferents from the midbrain raphe nuclei; and cholinergic fibres from the pontine and mesencephalic reticular formation.

The efferent fibres of the lateral geniculate nucleus pass principally to the primary visual cortex (area 17) in the banks of the calcarine sulcus. It is possible that additional small projections pass to extrastriate visual areas in the occipital lobe, possibly arising primarily in the interlaminar zones.

**Lateral dorsal nucleus**

The lateral dorsal nucleus is the most anterior of the dorsal tier of lateral nuclei. Its anterior pole lies within a splitting of the internal medullary lamina, and posteriorly it merges with the lateral posterior nucleus. Subcortical afferents to the lateral dorsal nucleus are from the pretectum and superior colliculus. It is connected with the cingulate, retrosplenial and posterior parahippocampal cortices, the presubiculum of the hippocampal formation, and the parietal cortex.

**Lateral posterior nucleus**

The lateral posterior nucleus, which lies dorsal to the ventral posterior nucleus, receives its subcortical afferents from the superior colliculus. It is reciprocally connected with the superior parietal lobe. Additional connections have been reported with the inferior parietal, cingulate and medial parahippocampal cortex.
The pulvinar corresponds to the posterior expansion of the thalamus, which overhangs the superior colliculus (Fig. 21.4). It has three major subdivisions, which are the medial, lateral and inferior pulvinar nuclei. The medial pulvinar nucleus is dorsomedial and consists of compact, evenly spaced, neurones. The inferior pulvinar nucleus lies laterally and inferiorly, and is traversed by bundles of axons in the mediolateral plane, an arrangement which confers a fragmented appearance of horizontal cords or sheets of cells separated by fibre bundles. The inferior pulvinar nucleus lies most inferiorly and laterally and is a more homogeneous collection of cells.

The subcortical afferents to the pulvinar are uncertain. Medial and lateral pulvinar nuclei may receive fibres from the superior colliculus. It has been suggested that the inferior pulvinar nucleus receives fibres both from the superior colliculus and directly from the retina and that it contains a complete retinotopic representation.

The cortical targets of efferent fibres from the pulvinar are widespread. In essence, the medial pulvinar nucleus projects to association areas of the parietotemporal cortex, whereas lateral and inferior pulvinar nuclei project to visual areas in the occipital and posterior temporal lobes. Thus, the inferior pulvinar nucleus connects with the striate and extrastriate cortex in the occipital lobe, and with visual association areas in the posterior part of the temporal lobe. The lateral pulvinar nucleus connects with extrastriate areas of the occipital cortex, with posterior parts of the temporal association cortex, and with the parietal cortex. The medial pulvinar nucleus connects with the inferior parietal cortex, with the posterior cingulate gyrus and with the widespread areas of the temporal lobe, including the posterior parahippocampal gyrus, perirhinal and entorhinal cortex. It also has extensive connections with prefrontal and orbitofrontal cortices. Similarly, the lateral pulvinar nucleus may also connect with the rostromedial prefrontal cortex.

Little is known of the functions of the pulvinar. The inferior pulvinar nucleus contains a complete retinotopic representation, and lateral and medial pulvinar nuclei also contain visually responsive cells. However, the latter nucleus, at least, is not purely visual – other modality responses can be recorded, and some cells may be polymodal. Given the complexity of functions of the association areas to which they project, particularly in the temporal lobe (e.g. perception, cognition and memory), it is likely that the role of the pulvinar in modulating these functions is equally complex.

Anteriorly, the major subdivisions of the pulvinar blend into a poorly differentiated region, within which several nuclear components have been recognized, including the anterior or oral pulvinar, the supragenulate-limitans nucleus and the posterior nuclei. The connectivity of this complex is also not well understood. It is recognized that different components receive subcortical afferents from the spinothalamic tract and the superior and inferior colliculi. Cortical connections centre primarily on the insula and adjacent parts of the parietal operculum posteriorly. Stimulation of this region has been reported to elicit pain, and large lesions may alleviate painful conditions. Similarly, excision of its cortical target in the parietal operculum, or small infarcts in this cortical region, may result in hypoalgesia.
The term intralaminar nuclei refers to collections of neurones within the internal medullary lamina of the thalamus (Fig. 21.4). Two groups of nuclei are recognized. The anterior (rostral) group is subdivided into central medial, paracentral and central lateral nuclei. The posterior (caudal) intralaminar group consists of the centromedian and parafascicular nuclei. The designations central medial and centromedian are open to confusion; however, they are an accepted part of the terminology of thalamic nuclei in common usage. The centromedian nucleus is much larger, is considerably expanded in man in comparison with other species, and is importantly related to the globus pallidus, deep cerebellar nuclei and motor cortex. Anteriorly, the internal medullary lamina separates the mediodorsal nucleus from the ventral lateral complex. It is occupied by the paracentral nucleus laterally, and the central medial nucleus ventromedially, as the two laminae converge towards the midline. A little more posteriorly, the central lateral nucleus appears dorsally in the lamina as the latter splits to enclose the lateral dorsal nucleus. More posteriorly, at the level of the ventral posterior nucleus, the lamina splits to enclose the ovoid centromedian nucleus. The smaller parafascicular nucleus lies more medially.

The anterior intralaminar nuclei, i.e. central medial, paracentral and central lateral, have reciprocal connections with widespread cortical areas. There is some evidence of areal preference: the central lateral nucleus projects mainly to parietal and temporal association areas; the paracentral nucleus to occipitotemporal and prefrontal cortex; and the central medial nucleus to orbitofrontal and prefrontal cortex and to the cortex on the medial surface. In contrast, the posterior nuclei, i.e. centromedian and parafascicular nuclei, have more restricted connections, principally with the motor, premotor and supplementary motor areas. Both anterior and posterior intralaminar nuclei also project to the striatum. Many cells throughout the anterior nuclei have branched axons, which pass to both the cortex and the striatum. Dual projections are less frequent in the posterior nuclei. The thalamostriate projection is topographically organized. The posterior intralaminar nuclei receive a major input from the internal segment of the globus pallidus. Additional afferents come from the pars reticulata of the substantia nigra, the deep cerebellar nuclei, the pedunculopontine nucleus of the midbrain, and possibly the spinothalamic tract. The anterior nuclei have widespread subcortical afferents. The central lateral nucleus receives afferents from the spinothalamic tract, and all component nuclei receive fibres from the brain stem reticular formation, the superior colliculus and several pretectal nuclei. Afferents to all intralaminar nuclei from the brain stem reticular formation include a prominent cholinergic pathway.

The precise functional role of the intralaminar nuclei is unclear. They appear
to mediate cortical activation from the brain stem reticular formation and to play a part in sensorimotor integration. Damage to the intralaminar nuclei may contribute to thalamic neglect, i.e. the unilateral neglect of stimuli originating from the contralateral body or extrapersonal space. This may arise particularly from unilateral damage to the centromedian–parafascicular complex. The latter has been targeted in humans for the neurosurgical control of pain and epilepsy. Bilateral injury to the posterior intralaminar nuclei leads to a kinetic mutism with apathy and loss of motivation. A second syndrome associated with damage involving the intralaminar nuclei is that of unilateral motor neglect, in which there is contralateral paucity of spontaneous movement and motor activity.
MIDLINE NUCLEI

There is considerable divergence between different authors as to which elements of the medial diencephalon constitute the nuclei of the midline thalamic group. In the present account, the midline group of nuclei includes those medial thalamic structures ventral to the central medial nucleus, i.e. the rhomboid and reuniens nuclei together with the parataenial nuclei more dorsolaterally.

The midline nuclei receive subcortical afferent fibres from the hypothalamus, the periaqueductal grey matter of the midbrain, the spinothalamic tract and the medullary and pontine reticular formation. They are the major thalamic target of ascending noradrenergic and serotonergic axons from the locus coeruleus and raphe nuclei respectively, and they also receive a cholinergic input from the midbrain. Efferents from the midline nuclei pass to the hippocampal formation, the amygdala and the nucleus accumbens. Additional thalamocortical axons reach the cingulate, and possibly orbitofrontal, cortex. The dual cortical and basal nuclear relationship of these nuclei has often led to their being considered a part of the intralaminar system. The cortical projections are reciprocal. The relationships of the midline nuclei clearly identify them as part of the limbic system. There is some evidence that they may play a role in memory and arousal, and, pathologically, may be important in the regulation of seizure activity.
RETICULAR NUCLEUS

The reticular nucleus is a curved lamella of large, deeply staining fusiform cells that wraps around the lateral margin of the thalamus, separated from it by the external medullary lamina. Anteriorly, it curves around the rostral pole of the thalamus to lie between it and the prethalamic nuclei, notably the bed nucleus of the stria terminalis. The nucleus is so named because it is criss-crossed by bundles of fibres which, as they pass between thalamus and cortex, produce a reticular appearance.

The nucleus is thought to receive collateral branches of corticothalamic, thalamocortical and probably thalamostriatal and pallidothalamic fibres as they traverse it. It receives an additional, probably cholinergic, afferent pathway from the nucleus cuneiformis of the midbrain. Broadly speaking, the afferents from the cortex and thalamus are topographically arranged. The reticular nucleus contains visual, somatic and auditory regions, each with a crude topographic representation of the sensorium concerned. Cells within these regions respond to visual, somatic or auditory stimuli with a latency suggesting that these properties arise from activation by thalamocortical axon collaterals. Only in areas where representations abut do cells show modality convergence.

The efferent fibres from the reticular nucleus pass into the body of the thalamus and are GABAergic. The projections into the main thalamic nuclei broadly, but not entirely, reciprocate the thalamoreticular connections. There may also be projections to the contralateral dorsal thalamus. The reticular nucleus is believed to function in gating information relayed through the thalamus.
The hypothalamus consists of only 4 cm$^3$ of neural tissue, or 0.3% of the total brain. Nevertheless, it contains the integrative systems that, via the autonomic and endocrine effector systems, control fluid and electrolyte balance, food ingestion and energy balance, reproduction, thermoregulation, and immune and many emotional responses.

The hypothalamus extends from the lamina terminalis to a vertical plane posterior to the mammillary bodies, and from the hypothalamic sulcus to the base of the brain beneath the third ventricle. It lies beneath the thalamus (Fig. 21.3) and anterior to the tegmental part of the subthalamus and the mesencephalic tegmentum (Figs 21.7, 21.8)). Laterally, it is bordered by the anterior part of the subthalamus, internal capsule and optic tract. Structures in the floor of the third ventricle reach the pial surface in the interpeduncular fossa. From anterior to posterior they are the optic chiasma, the tuber cinereum, tuberal eminences and the infundibular stalk, the mammillary bodies and the posterior perforated substance. The latter lies in the interval between the diverging crura cerebri, and is pierced by small central branches of the posterior cerebral arteries. It contains the small interpeduncular nucleus, which receives terminals of the fasciculus retroflexus of both sides, and has other connections with the mesencephalic reticular formation and mammillary bodies.
Fig. 21.7. The inferior aspect of the hypothalamus and surrounding structures.
(Photograph by Kevin Fitzpatrick on behalf of GKT School of Medicine, London.)
Fig. 21.8 The hypothalamic region of the left cerebral hemisphere viewed from the medial aspect and dissected to display the major hypothalamic nuclei. In the upper diagram the medially placed nuclear groups have been removed; in the lower diagram both lateral and medial groups are included. Lateral to the fornix and the mammillothalamic tract is the lateral hypothalamic region, in which the tuberomammillary nucleus is situated posteriorly, and the lateral preoptic nucleus rostrally. Surrounding the fornix is the perifornical nucleus, which joins the lateral hypothalamic area with the posterior hypothalamic nucleus. The medially placed nuclei (yellow) fill in much of the region between the mammillothalamic tract and the lamina terminalis, but also project caudal to the tract. The lateral tuberal nuclei are situated ventrally, largely in the lateral hypothalamic area. The supraoptic nuclei may form three rather separate parts. The intermediate nuclei form three groups between the supraoptic and paraventricular nuclei.

The mammillary bodies are smooth, hemispherical, pea-sized eminences, lying side by side, anterior to the posterior perforated substance, each with nuclei enclosed in fascicles of fibres derived largely from the fornix. The tuber cinereum, between the mammillary bodies and the optic chiasma, is a convex mass of grey matter. From it, the median, conical, hollow infundibulum becomes continuous ventrally with the posterior lobe of the pituitary. Around the base of the infundibulum is the median eminence, which is demarcated by a shallow tubero-infundibular sulcus.

Hypothalamic lesions have long been linked with widespread and bizarre endocrine syndromes and with metabolic, visceral, motor and emotional disturbances. The hypothalamus has major interactions with the neuroendocrine system and the autonomic nervous system, integrating responses to both internal and external afferent stimuli with the complex analysis of the world provided by the cerebral cortex.

The hypothalamus controls the endocrine system in a variety of ways: through magnocellular neurosecretory projections to the posterior pituitary; through parvocellular neurosecretory projections to the median eminence (these control the endocrine output of the anterior pituitary and thereby the peripheral endocrine organs); and via the autonomic nervous system. The posterior pituitary neurohormones, vasopressin and oxytocin, are primarily involved in the control of osmotic homeostasis and various aspects of reproductive function, respectively. Through its effects on the anterior pituitary, the hypothalamus influences the thyroid gland (thyroid stimulating hormone, TSH), suprarenal cortex (adrenocorticotrophic
hormone, ACTH), gonads (luteinizing hormone, LH; follicle stimulating hormone, FSH; prolactin), mammary gland (prolactin), and the processes of growth and metabolic homeostasis (growth hormone, GH).

The hypothalamus influences both parasympathetic and sympathetic divisions of the autonomic nervous system. In general, parasympathetic effects predominate when the anterior hypothalamus is stimulated; sympathetic effects depend more on the posterior hypothalamus.

Stimulation of the anterior hypothalamus and paraventricular nucleus can cause decreased blood pressure and decreased heart rate. Stimulation in the anterior hypothalamus induces sweating and vasodilatation (and thus heat loss) via projections that pass through the medial forebrain bundle to autonomic centres in the brain stem and spinal cord. Damage to the anterior hypothalamus, e.g. during surgery for suprasellar extensions of pituitary tumours, can result in an uncontrorollable rise in body temperature. Projections to the ventromedial hypothalamus conjointly regulate food intake. Stimulation in the posterior part of the hypothalamus induces sympathetic arousal which produces vasoconstriction, piloerection, shivering and increased metabolic heat production. Circuitry mediating shivering is located in the dorsomedial posterior hypothalamus. This does not imply the existence of discrete parasympathetic and sympathetic ‘centres’. Stimuli in many different parts of the hypothalamus can cause profound changes in heart rate, cardiac output, vasomotor tone, peripheral resistance, differential blood flow in organs and limbs, the frequency and depth of respiration, motility and secretion in the alimentary tract, erection and ejaculation.

HYPOTHALAMIC NUCLEI

The hypothalamus contains a number of neuronal groups that have been classified on phylogenetic, developmental, cytoarchitectonic, synaptic and histochemical grounds into named nuclei, many of which are not very clearly delimited, especially in the adult. While it contains a few large myelinated tracts, many of the connections are diffuse and unmyelinated, and the precise paths of many afferent, efferent, and intrinsic connections are uncertain.

The hypothalamus can be divided anteroposteriorly into chiasmatic (supraoptic), tuberal (infundibulo-tuberal) and posterior (mammillary) regions, and mediolaterally into periventricular, intermediate (medial), and lateral zones. Between the intermediate and lateral zones is a paramedian plane, which contains the prominent myelinated fibres of the column of the fornix, the mammillothalamic tract and the fasciculus retroflexus. For this reason, some authors group the periventricular and intermediate zones as a single medial zone. These divisions are artificial and functional systems cross them. The main nuclear groups and myelinated tracts are illustrated in Figures 21.8 and 21.9.
The periventricular zone of the hypothalamus borders the third ventricle. In the anterior wall of the ventricle is the vascular organ of the lamina terminalis (OVLT, organum vasculosum), which is continuous dorsally with the median preoptic nucleus and subfornical organ. On each side in the chiasmatic region are: part of the preoptic...
nucleus; the small, sexually dimorphic suprachiasmatic nucleus; periventricular neurones, which are medial to, and blend with, the paraventricular nucleus. In the tuberal region, the periventricular cell group expands around the base of the third ventricle to form the arcuate nucleus, which overlies the median eminence. In the posterior region, the narrow periventricular zone is continuous laterally with the posterior hypothalamic area and behind that with midbrain periaqueductal grey matter. The periventricular zone also contains a prominent periventricular fibre system.

**Suprachiasmatic nucleus**

Although it contains only a few thousand neurones, the suprachiasmatic nucleus is a remarkable structure. It appears to be the neural substrate for day–night cycles in motor activity, body temperature, plasma concentration of many hormones, renal secretion, sleeping and waking, and many other variables. Lesions of the suprachiasmatic region lead to a disordered sleep–wake cycle.

The suprachiasmatic nucleus has two principal subdivisions, ventrolateral and dorsomedial. Retinal fibres terminate in the ventrolateral subdivision, characterized by neurones immunoreactive for vasoactive intestinal polypeptide (VIP). This appears to be a general input zone, which also receives afferents from the midbrain raphe and parts of the lateral geniculate nucleus of the thalamus. The dorsomedial subdivision has relatively sparse afferent innervation, and characteristically contains parvocellular neurones immunoreactive for arginine vasopressin (AVP). Neurones within the suprachiasmatic nuclei that receive direct retinal input do not respond to pattern, movement or colour. Instead, they operate as luminance detectors, responding to the onset and offset of light, and their firing rates vary in proportion to light intensity, thereby synchronizing to the light–dark cycle.

The suprachiasmatic nucleus receives glutamatergic afferents from retinal ganglion cells that entrain the rhythm to the light–dark cycle, but these are not essential for the production of the rhythm, which persists in the blind. It contains many different neurotransmitters including vasopressin, VIP, neuropeptide Y (NPY) and neotensin. Axons from the suprachiasmatic nucleus pass to many other hypothalamic nuclei including the paraventricular, ventromedial, dorsomedial and arcuate nuclei.

The suprachiasmatic nucleus also influences the activity of upper spinal preganglionic sympathetic neurones. These neurones in turn project to superior cervical ganglion neurones which project to the pineal gland. In the pineal, which contains modified photoreceptors, circadian variation in the postganglionic sympathetic input causes parallel variation in pineal N-acetyltransferase activity and thus pineal melatonin production. The role of the pineal gland in man is uncertain: pineal tumours can influence reproductive development, and administration of melatonin has been advocated to alleviate jet-lag.

Parvocellular neurosecretory neurones lie within the periventricular zone, in particular the medial parvocellular part of the paraventricular nucleus, and the arcuate nucleus. The arcuate nucleus is median in the post-infundibular part of the tuber cinereum. It extends forward into the median eminence and almost encircles the infundibular base, but does not meet anteriorly, where the infundibulum adjoins the median part of the optic chiasma. Its numerous neurones are all small and round in coronal section, and oval or fusiform in sagittal section. No glial layer intervenes between the nucleus and
the ependymal tanyocytes lining the infundibular recess of the third ventricle. Circadian variation in the secretion of all anterior pituitary hormones suggests that projections from the suprachiasmatic nucleus must reach parvocellular neurosecretory neurones. Afferents from the limbic system probably mediate the widespread effects of stress, and serotonin and noradrenaline from the brain stem influence the output of most anterior pituitary hormones. The axons of parvocellular neurones converge on the infundibulum, forming a tubero-infundibular tract, which ends on the capillary loops that form the hypophysial portal vessels.

Neurones producing growth hormone-releasing hormone (GHRH) are largely restricted to the arcuate nucleus. Some extend dorsally into the periventricular nucleus and laterally into the retrochiasmatic area. Their fibres run through the periventricular region to the neurovascular zone of the median eminence. The neurones receive afferent information from glucose receptors in the ventromedial nucleus. Inputs from the hippocampal–amygdala–septal complex could explain the release of GH during stress. In man, midline defects such as septo-optic dysplasia are associated with defective growth hormone secretion. Dopamine has a stimulatory effect.

Neurones producing somatostatin (growth hormone release-inhibiting hormone) are located in the periventricular nucleus. GHRH and somatostatin are secreted in intermittent (3–5 hour) reciprocal pulses, but the origin of the pulses is unclear. A large pulse of GH is secreted at the onset of slow wave sleep. Somatostatin also inhibits release of pituitary thyroid-stimulating hormone (TSH).

Neurones producing GHRH and projecting to the median eminence are also located in the periventricular and arcuate nuclei. Other GHRH neurones are found in the periventricular preoptic area, but these appear to project to the vascular organ of the lamina terminalis. Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are secreted in circhoral (hourly) pulses, which are stimulated by GHRH, and are influenced by central monoamine and GABA, by oestrogen and progesterone acting indirectly through other neurones, by corticotrophin-releasing factor, and by endogenous opioids.

Corticotrophin-releasing hormone (CRH) is located primarily in parvocellular paraventricular neurones. They are profoundly stimulated by neurogenic (limbic input) and hypoglycaemic (ventromedial nucleus) stress, and are also controlled by negative feedback by cortisol.

Thyrotrophin-releasing hormone (TRH) neurones are rather more widely distributed in the periventricular, ventromedial and dorsomedial nuclei. TRH release is influenced by core temperature, sensed in the anterior hypothalamus, and by negative feedback of thyroid hormones. It stimulates release of pituitary TSH and also acts to excite cold-sensitive, and to inhibit warm-sensitive neurones in the preoptic area.

Other tubero-infundibular arcuate neurones contain neuropeptide Y (NPY) and neurotensin. Arcuate neurones containing pro-opiomelanocortin peptides project to the periventricular nucleus rather than the median eminence.

In addition to these peptide-containing cells, dopamine neurones in the arcuate nucleus (A12 group) have terminals in the median eminence and infundibulum.
Dopamine acts as the principal prolactin-release inhibiting hormone, and also inhibits secretion of TSH (likewise, TSH acts as a prolactin-releasing hormone). Noradrenergic terminals are found in the median eminence, where they may act largely in a paracrine manner.

The intermediate zone of the hypothalamus contains the best differentiated nuclei. These are: the paraventricular and supraoptic nuclei; ‘intermediate’ nuclear groups, which show sexual dimorphism; ventromedial and dorsomedial nuclei; the mammillary body; and tuberomammillary nuclei. Magnocellular neurosecretory neurones are found in the supraoptic nucleus, paraventricular nucleus, and as isolated clusters of cells between them.

**Supraoptic and paraventricular nuclei**

The supraoptic nucleus, curved over the lateral part of the optic chiasma, contains a uniform population of large neurones. Behind the chiasma, a thin plate of cells in the floor of the brain forms the retrochiasmatic part.

Supraoptic neurones synthesize vasopressin, and they all appear to project to the neurohypophysis. The magnocellular vasopressin neurones detect as little as 1% increase in the osmotic pressure of the blood and stimulate release of vasopressin from the posterior pituitary. A fall in blood volume or blood pressure of greater than 5–10% stimulates the release of vasopressin and the urge to drink. These responses are mediated via volume receptors in the walls of the great veins and atria and baroreceptors in the carotid sinus which all project via the vagus and glossopharyngeal nerves to the nucleus tractus solitarius and thence to the magnocellular nuclei. A biochemical defect in vasopressin production, or interruption of the supraopticohypophysial pathway (e.g. due to a head injury), can cause cranial diabetes insipidus.

The paraventricular nucleus extends from the hypothalamic sulcus downward across the medial aspect of the column of the fornix, its ventrolateral angle reaching towards the supraoptic nucleus. Its neurones are more diverse. Magnocellular neurones, which project to the neurohypophysis, tend to lie laterally; parvocellular neurones, which project to the median eminence and infundibulum, lie more medially; intermediate-sized neurones, which may project caudally, lie posteriorly. The axons of the paraventricular magnocellular neurones pass towards the supraoptic nucleus (paraventriculohypophysial tract), where they join axons of supraoptic neurones to form a supraopticohypophysial tract. This runs down the infundibulum, superficially, and into the neural lobe, where the axons are distended and branch repeatedly around the capillaries. Vasopressin and oxytocin are produced by separate neurones: vasopressin neurones tend to cluster in the ventrolateral part of the paraventricular nucleus and the oxytocin neurones lie around them.

The hypothalamus is essential for the control of pituitary oxytocin, gonadotrophin and prolactin secretion. The release of oxytocin from neurosecretory nerve terminals in the neurohypophysis induces contraction of the uterus and of the myoepithelial cells that surround the mammary gland alveoli. Two neuroendocrine reflexes are involved. Stretching of the cervix of the uterus during childbirth stimulates a multisynaptic afferent pathway that passes via the pelvic plexus, anterolateral column and brain stem to the magnocellular oxytocin neurones (the Ferguson reflex). This is a positive
feedback mechanism, which is terminated by the birth of the child. The milk ejection reflex is evoked by suckling of the nipple, which activates intercostal nerves and, thereby, an afferent connection to the hypothalamus. The reflex can be both conditioned to a baby’s cry and inhibited by stress.

At the tuberal level, the ventromedial nucleus is well defined by a surrounding neurone-poor zone, but the dorsomedial nucleus above it is much less distinct. The ventromedial nucleus contains neurones receptive to plasma levels of glucose and other nutrients and receives visceral somatic afferents via the nucleus tractus solitarius. The lateral hypothalamus receives olfactory afferents, which act as important food signals. Both areas receive extensive inputs from limbic structures. Stimulation and lesion experiments, together with human case studies, suggest that the ventromedial nuclei act together as a 'satiety centre'. Bilateral ventromedial nucleus damage promotes overeating (hyperphagia), and restricting food intake may provoke rage-like outbursts. The resultant obesity is usually coupled with hyposexuality (Fröhlich syndrome). Interestingly, in infants, ventromedial damage can lead to emaciation despite apparent normal feeding. Experimental lesions in the lateral hypothalamus promote hypophagia or aphagia, while stimulation can prolong feeding, supporting the concept of a lateral hypothalamic 'feeding centre'.

The ventromedial nucleus, lateral hypothalamic area and paraventricular nucleus also influence intermediate metabolism through the autonomic and endocrine systems. These appear to complement the effects on feeding behaviour. Thus, ventromedial stimulation facilitates glucagon release and increases glycogenolysis, gluconeogenesis and lipolysis, whereas lateral hypothalamic stimulation causes insulin release and the opposite metabolic effects. Lesions of the ventromedial nucleus also cause increased vagal and decreased sympathetic tone.

The medial mammillary nuclei, which form the bulk of the mammillary bodies, are very prominent. The distinct existence of a lateral mammillary nucleus is controversial, though a group of larger cells does occur along the lateral border of the medial mammillary nucleus. Lateral to this is the tuberomammillary nucleus, which gives rise to widespread axons that diffusely innervate the entire cerebral cortex, hypothalamus and brain stem.

The lateral zone of the hypothalamus forms a continuum that runs from the preoptic nucleus through the lateral hypothalamic area to the posterior hypothalamus. In the tuberal region, the lateral tuberal nuclei are large and well defined and surrounded by fine fibres.
CONNECTIONS OF THE HYPOTHALAMUS

The hypothalamus has reciprocal interaction with the rest of the body via two (possibly three) quite distinct routes: neural connections, the bloodstream and (probably) the CSF.

Some hypothalamic neurones have specific receptors that sense the temperature, osmolarity, glucose, free fatty acid, and hormone content of the blood. Neurosecretory neurones secrete neurohormones into the blood. These control the anterior pituitary and act on organs such as the kidney, breast, uterus and blood vessels. Some of the neural connections, especially those to the mammillary bodies, form discrete myelinated fascicles, but most are diffuse, unmyelinated and their origin and termination are uncertain. Most pathways are multisynaptic and many of the synapses on hypothalamic neurones are derived from intrinsic interneurones.

Broadly, neural inputs to the hypothalamus are derived from the ascending visceral and somatic sensory systems, the visual and olfactory systems, and numerous tracts from the brain stem, thalamus, 'limbic' structures and neocortex. Efferent neural projections are reciprocal to most of these and, in particular, they impinge on and control the central origins of autonomic nerve fibres. The hypothalamus therefore exerts control via the autonomic and endocrine systems and through its connections to the telencephalon.

Afferent connections

The hypothalamus receives visceral, gustatory and somatic sensory information from the spinal cord and brain stem. It receives largely polysynaptic projections from the nucleus tractus solitarius, probably directly and indirectly via the parabrachial nucleus and medullary noradrenergic cell groups (ventral noradrenergic bundle); collaterals of lemniscal somatic afferents (to the lateral hypothalamus); and projections from the dorsal longitudinal reticular formation. Many enter via the medial forebrain bundle (Fig. 21.9) and periventricular fibre system. Others converge in the midbrain tegmentum, forming the mammillary peduncle to the mammillary body.

The major forebrain inputs to the hypothalamus are derived from structures in the limbic system, including the hippocampal formation, amygdala and septum, and from the piriform lobe and adjacent neocortex. These connections, which are reciprocal, form prominent fibre systems, i.e. the fornix, stria terminalis, and ventral amygdalofugal tracts.

The hippocampal formation, in particular the subiculum and CA1, is reciprocally connected to the hypothalamus by the fornix, a complex tract that also contains commissural connections. As the fornix curves ventrally towards the anterior commissure it is joined by fascicles from the cingulate
gyrus, indusium griseum and the septal area. It divides around the anterior commissure into pre- and postcommissural parts. The precommissural fornix is distributed to the septum and preoptic hypothalamus, and the septum in turn sends numerous fibres to the hypothalamus. The postcommissural fornix passes ventrally and posteriorly through the hypothalamus to the medial mammillary nucleus. In its course it gives off many fibres to the medial and lateral hypothalamic nuclei.

The amygdala innervates most hypothalamic nuclei anterior to the mammillary bodies. Its corticomedial nucleus innervates preoptic and anterior hypothalamic areas and the ventromedial hypothalamus. The central nuclei project to the lateral hypothalamus. The fibres reach the hypothalamus by two routes. The short ventral amygdalofugal path passes medially over the optic tract, beneath the lentiform complex, to reach the hypothalamus. The long curved stria terminalis runs parallel to the fornix, separated from it by the lateral ventricle, passes through the bed nucleus of the stria terminalis, and is then distributed to the anterior hypothalamus via the medial forebrain bundle.

Olfactory afferents reach the hypothalamus largely via the nucleus accumbens and septal nuclei, and most terminate in the lateral hypothalamus. Visual afferents leave the optic chiasma and pass dorsally into the suprachiasmatic nucleus. No auditory connections have been identified, though it is clear that such stimuli influence hypothalamic activity. However, many hypothalamic neurones respond best to complex sensory stimuli, suggesting that sensory information reaching the neocortex has converged and been processed by the amygdala, hippocampus and neocortex. Neocortical corticohypothalamic afferents to the hypothalamus are poorly defined, but probably arise from frontal and insular cortices. Some may relay in the mediodorsal thalamic nucleus and project into the hypothalamus via the periventricular route. Other direct corticohypothalamic fibres may end in lateral, dorsomedial, mammillary and posterior hypothalamic nuclei, but all these connections are questioned.

Like the rest of the forebrain, the hypothalamus also receives diffuse aminergic inputs from the locus coeruleus and raphe nuclei. In addition, it receives input from the ventral tegmental ascending cholinergic pathway; a noradrenergic input to dorsomedial, periventricular, paraventricular, supraoptic and lateral hypothalamic nuclei from the ventral tegmental noradrenergic bundle, and fibres from the mesolimbic dopaminergic system. Group A11 innervates the medial hypothalamic nuclei, and groups A13 and A14 supply the dorsal and rostral hypothalamic nuclei. Many of these fibres also run in the medial forebrain bundle.

The medial forebrain bundle is a loose grouping of fibre pathways that mostly run longitudinally through the lateral hypothalamus (Fig. 21.9). It connects forebrain autonomic and limbic structures with the hypothalamus and brain.
stem, receiving and giving small fascicles throughout its course. It contains descending hypothalamic afferents from the septal area and orbitofrontal cortex, ascending afferents from the brain stem, and efferents from the hypothalamus.

**Efferent connections**

Hypothalamic efferents include reciprocal paths to the limbic system, descending polysynaptic paths to autonomic and somatic motor neurones, and neural and neurovascular links with the pituitary.

Septal areas and the amygdaloid complex have reciprocal hypothalamic connections along the paths described above. The medial pre-optic and anterior hypothalamic areas give short projections to nearby hypothalamic groups. The ventromedial nucleus has more extensive projections that pass via the medial forebrain bundle to the bed nucleus of the stria terminalis, basal nucleus of Meynert, central nucleus of the amygdala, and midbrain reticular formation. The posterior hypothalamus projects largely to the midbrain central grey matter. Some tuberal and posterior lateral hypothalamic neurones project directly to the entire neocortex and appear to be essential for maintaining cortical arousal, but the topography of these projections is unclear.

Hypothalamic neurones projecting to autonomic neurones are found in the paraventricular nucleus (oxytocin and vasopressin neurones), perifornical and dorsomedial nuclei (atrial natriuretic peptide neurones), lateral hypothalamic area (α-melanocyte-stimulating hormone; α-MSH neurones), and zona incerta (dopamine neurones). These fibres run through the medial forebrain bundle into the tegmentum, ventrolateral medulla and dorsal lateral funiculus of the spinal cord. In the brain stem, fibres innervate the parabrachial nucleus, nucleus ambiguus, nucleus of the solitary tract and dorsal motor nucleus of the vagus. In the spinal cord, they end on sympathetic and parasympathetic preganglionic neurones in the intermediolateral column. Both oxytocin- and vasopressin-containing fibres can be traced to the most caudal spinal autonomic neurones.

The medial mammillary nucleus gives rise to a large ascending fibre bundle, which diverges into the mammillothalamic and mammillotegmental tracts (Fig. 21.9). The mammillothalamic tract ascends through the lateral hypothalamus to reach the anterior thalamic nuclei, whence massive projections radiate to the cingulate gyrus. The mammillotegmental tract curves inferiorly into the midbrain ventral to the medial longitudinal fasciculus, and is distributed to tegmental reticular nuclei.
PITUITARY GLAND

The pituitary gland, or hypophysis cerebri (Fig. 21.10; see Fig. 16.7), is a reddish-grey, ovoid body, about 12 mm in transverse and 8 mm in anteroposterior diameter, and with an average adult weight of 500 mg. It is continuous with the infundibulum, a hollow, conical, inferior process from the tuber cinereum of the hypothalamus. It lies within the pituitary fossa of the sphenoid bone, where it is covered superiorly by a circular diaphragma sellae of dura mater. The latter is pierced centrally by an aperture for the infundibulum, and separates the anterior superior aspect of the pituitary from the optic chiasma. Inferiorly, the pituitary is separated from the floor of the fossa by a venous sinus that communicates with the circular sinus. The meninges blend with the pituitary capsule and are not separate layers.

The pituitary has two major parts, the neurohypophysis and adenohypophysis, which differ in their origin, structure and function. The neurohypophysis is a diencephalic downgrowth connected with the hypothalamus. The adenohypophysis is an ectodermal derivative of the stomatodeum. Both include parts of the infundibulum (whereas the older terms ‘anterior lobe’ and ‘posterior lobe’ do not). The infundibulum has a central infundibular stem, which contains neural hypophysial connections and is continuous with the median eminence of the tuber cinereum. Thus, the term neurohypophysis includes the median eminence, infundibular stem and neural lobe or pars posterior. Surrounding the infundibular stem is the pars tuberalis, a component of the adenohypophysis. The main mass of the adenohypophysis may be divided into...
the pars anterior (pars distalis) and the pars intermedia, which are separated in fetal and early postnatal life by the hypophysial cleft, a vestige of Rathke’s pouch, from which it develops. Usually obliterated in childhood, remnants may persist in the form of cystic cavities often present near the adenoneurohypophysial frontier and sometimes invading the neural lobe. The human pars intermedia is rudimentary. It may be partially displaced into the neural lobe, and so it has been included in the anterior and posterior parts by different observers. Apart from this equivocation, which is of little significance, the pars anterior and pars posterior may be equated with the anterior and posterior lobes. When the associated infundibular parts continuous with these lobes are included, the names adenohypophysis and neurohypophysis become appropriate, and will be used here as follows: Neurohypophysis includes the pars posterior (pars nervosa, posterior or neural lobe), infundibular stem and median eminence. Adenohypophysis includes the pars anterior (pars distalis or glandularis), pars intermedia and pars tuberalis.

**Neurohypophysis**

In early fetal life the neurohypophysis contains a cavity continuous with the third ventricle. Axons arising from groups of hypothalamic neurones (e.g. the magnocellular neurones of the supraoptic and paraventricular nuclei) terminate in the neurohypophysis. The long magnocellular axons pass to the main mass of the neurohypophysis. They form the neurosecretory hypothalamohypophysial tract and terminate near the sinusoids of the posterior lobe. Some smaller parvocellular neurones in the periventricular zone have shorter axons, and end in the median eminence and infundibular stem among the superior capillary beds of the venous portal circulation. These small neurones produce releasing and inhibitory hormones, which control the secretory activities of the adenohypophysis via its portal blood supply.

The neurohormones stored in the main part of the neurohypophysis are vasopressin (antidiuretic hormone; ADH), which controls reabsorption of water by renal tubules (see Ch. 74), and oxytocin, which promotes the contraction of uterine smooth muscle (see Ch. 77) in childbirth and the ejection of milk from the breast during lactation. Storage granules containing active hormone polypeptides bound to a transport glycoprotein, neurophysin, pass down axons from their site of synthesis in the neuronal somata (Fig. 21.11).
The thin, non-myelinated axons of the neurohypophysis are ensheathed by typical astrocytes in the infundibulum (Fig. 21.12). Near the posterior lobe, astrocytes are replaced by pituicytes, which constitute most of the non-excitable tissue in the neurohypophysis. Pituicytes are dendritic neuroglial cells of variable appearance, often with long processes running parallel to adjacent axons. Typically, their cytoplasmic processes end on the walls of capillaries and sinusoids between nerve terminals. Axons also end in perivascular spaces; they lie close to the walls of sinusoids, but remain separated from them by two basal laminae, one around the nerve endings and the other underlying the fenestrated endothelial cells. The spaces between the basal laminae are occupied by fine collagen fibrils.
The adenohypophysis is highly vascular. It consists of epithelial cells of varying size and shape arranged in cords or irregular follicles, between which lie thin-walled vascular sinusoids supported by a delicate reticular connective tissue (Figs 21.11, 21.12). Most of the hormones synthesized by the adenohypophysis are trophic. They include the peptides growth hormone (GH), involved in the control of body growth, and prolactin (PRL), which stimulates both growth of breast tissue and milk secretion. Glycoprotein trophic hormones are the large pro-opiomelanocortin precursor of adrenocorticotropic hormone (ACTH), which controls the secretion of certain suprarenal
cortical hormones; thyroid-stimulating hormone (TSH); follicle-stimulating hormone (FSH), which stimulates growth and secretion of oestrogens in ovarian follicles and spermatogenesis (acting on testicular Sertoli cells); and luteinizing hormone (LH), which induces progesterone secretion by the corpus luteum and testosterone synthesis by Leydig cells in the testis. Pro-opiomelanocortin is cleaved into a number of different molecules including ACTH. β-Lipotropin is released from the pituitary, but its lipolytic function in humans is uncertain. β-Endorphin is another cleavage product released from the pituitary.

The epithelial endocrine cells, which secrete the different adenohypophysial hormones, are distinguished in part by their differing affinities for acidic and basic dyes. Cells staining strongly are described as chromophils, those with low affinity for dyes are chromophobes. Chromophils that stain strongly with acidic dyes are classed as acidophils, whereas basophils stain strongly with basic dyes; the latter are more prevalent in the central part of the gland. Classification according to the hormones synthesized divides cells into somatotrophs (GH-secreting acidophils, the most numerous chromophil type); lactotrophs (prolactin-secreting acidophils, which are dominant in pregnancy and hypertrophy during lactation); gonadotrophs (FSH- and LH-secreting basophils); thyrotrophs (TH-secreting basophils); and corticotrophs (ACTH-secreting basophils). Chromophobes are thought to be quiescent or degranulated chromophils, or immature precursor cells; they constitute up to half of the cells of the adenohypophysis.

Neurones that secrete the peptides and amines that control the anterior lobe are widely distributed within the hypothalamus. They are situated mainly in the medial zone, in the arcuate nucleus, medial parvocellular part of the paraventricular nucleus, and periventricular nucleus.

The pars intermedia contains follicles of chromophobe cells that surround cyst-like structures lined by epithelium and filled, to varying degrees, with glycosylated colloidal material. Secretory products of this region may include cleavage products of pro-opiomelanocortin but their functional significance is uncertain. The pars tuberalis contains a large number of blood vessels, between which are cords or clusters of gonadotrophs and undifferentiated cells.

A small collection of adenohypophysial tissue lies in the mucoperiosteum of the human nasopharyngeal roof. By 28 weeks in utero it is well vascularized and capable of secretion, receiving blood from the systemic vessels of the nasopharyngeal roof. At this stage it is covered posteriorly by fibrous tissue. This is replaced in the second half of fetal life by venous sinuses, and a trans-sphenoidal portal venous system develops, bringing the nasopharyngeal tissue under the same hypothalamic control as the cranial adenohypophysial tissue. The peripheral vascularity of the pharyngeal hypophysis persists until about the fifth year. The organ is then reinvested by fibrous tissue and presumed to be again controlled by factors present in systemic blood. Though it does not change in size after birth in males, in females it becomes smaller, returning to natal volume during the fifth decade, when once again it may be controlled via a trans-sphenoidal extension of the hypothalamohypophysial portal venous system. The human pharyngeal hypophysis may be a reserve of potential adenohypophysial tissue, which may be stimulated, particularly in females, to synthesize and secrete adenohypophysial hormones in middle age, when intracranial adenohypophysial tissue is beginning to fail.
**Vessels of the pituitary**

The arteries of the pituitary arise from the internal carotid arteries via a single inferior and several superior hypophysial arteries on each side. The former come from the cavernous part of the internal carotid artery, the latter from its supraclinoid part and from the anterior and posterior cerebral arteries. The inferior hypophysial arteries divide into medial and lateral branches, which anastomose across the midline and form an arterial ring around the infundibulum. Fine branches from this circular anastomosis enter the neurohypophysis to supply its capillary bed. The superior hypophysial arteries supply the median eminence, upper infundibulum and, via arteries of the trabeculae, the lower infundibulum. A confluent capillary net, extending through the neurohypophysis, is supplied by both sets of hypophysial vessels. Reversal of flow can occur in cerebral capillary beds lying between the two supplies.

The arteries of the median eminence and infundibulum end in characteristic sprays of capillaries, which are most complex in the upper infundibulum. In the median eminence these form an external or ‘mantle’ plexus and an internal or ‘deep’ plexus. The external plexus, fed by the superior hypophysial arteries, is continuous with the infundibular plexus and is drained by long portal vessels, which descend to the pars anterior. The internal plexus lies within and is supplied by the external plexus. It is continuous posteriorly with the infundibular capillary bed and, like the external plexus, is drained by long portal vessels. Short portal vessels run from the lower infundibulum to the pars anterior. Both types of portal vessel open into vascular sinusoids, which lie between the secretory cords in the adenohypophysis and provide most of its blood. There is no direct arterial supply. The portal system carries hormone-releasing factors, probably elaborated in parvocellular groups of hypothalamic neurones, and these control the secretory cycles of cells in the pars anterior. The pars intermedia appears to be avascular.

There are three possible routes for venous drainage of the neuro-hypophysis: to the adenohypophysis, via long and short portal vessels; into the dural venous sinuses, via the large inferior hypophysial veins; and to the hypothalamus, via capillaries passing to the median eminence. The venous drainage carries hypophysial hormones from the gland to their targets and also facilitates feedback control of secretion. However, venous drainage of the adenohypophysis appears restricted: few vessels connect it directly to the systemic veins and so the routes by which blood leaves remain obscure.
**SUBTHALAMUS**

The subthalamus is a complex region of nuclear groups and fibre tracts (Fig. 22.13). The main nuclear groups are the subthalamic nucleus, the reticular nucleus, the zona incerta, the fields of Forel and the pregeniculate nucleus. The rostral poles of the red nucleus and substantia nigra also extend into this area.

The main subthalamic tracts are: the upper parts of the medial, spinal and trigeminal lemnisci and the solitariothalamic tract, all approaching their terminations in the thalamic nuclei; the dentatothalamic tract from the contralateral superior cerebellar peduncle accompanied by ipsilateral rubrothalamic fibres; the fasciculus retroflexus; the fasciculus lenticularis; the fasciculus subthalamicus; the ansa lenticularis; fascicles from the prerubral field (H field of Forel); the continuation of the fasciculus lenticularis (in the H₂ field of Forel); the fasciculus thalamicus (the H₁ field of Forel).

**SUBTHALAMIC NUCLEUS**

The subthalamic nucleus is structurally and functionally related to the basal ganglia and is therefore considered with them in Chapter 22.
**ZONA INCERTA AND FIELDS OF FOREL**

The zona incerta is an aggregation of small cells that lies between the ventral part of the external medullary lamina of the thalamus and the cerebral peduncle. It is linked to the reticular nucleus dorsolaterally. More medially is a scattered group of cells in a matrix of fibres known as the H field of Forel. Field $H_1$ of Forel consists of the thalamic fasciculus, which lies dorsal to the zona incerta. Field $H_2$ of Forel contains the fasciculus lenticularis, and lies ventrally, between the zona incerta and the subthalamic nucleus.

The zona incerta receives fibres from the sensorimotor cortex, the pregeniculate nucleus, the deep cerebellar nuclei, the trigeminal nuclear complex and the spinal cord. It projects to the spinal cord and the pretectal region. Its functions are unknown.

The neurones of the H field of Forel receive afferents from, the spinal cord, the reticular formation of the brain stem and possibly the internal segment of the globus pallidus. They may project to the spinal cord. Like the zona incerta, their functions are unknown.

In addition to terminal parts of the lemniscal, dentatothalamic and rubrothalamic tracts, the subthalamus contains massive fibre tracts derived from the globus pallidus. The fasciculus lenticularis is the dorsal component of pallidofugal fibres that traverse the internal capsule. It turns medially near the medial aspect of the capsule, partly intermingled with the dorsal zone of the subthalamic nucleus and the ventral part of the zona incerta, where the fasciculus traverses the $H_2$ field of Forel. Reaching the medial border of the zona incerta, the fasciculus intermingles with fibres of the ansa lenticularis, scattered elements of the prerubral nucleus, and dentatothalamic and rubrothalamic fibres. This merging of diverse pathways and associated cell groups is variously called the prerubral, tegmental or H field of Forel.

The ansa lenticularis has a complex origin from both parts of the globus pallidus and possibly other adjacent structures. It curves medially round the ventral border of the internal capsule, and continues dorsomedially to mingle with other fibres in the prerubral field. Some fibres in the fasciculus lenticularis and ansa lenticularis synapse in the subthalamic nucleus, prerubral field and zona incerta. The remainder continue laterally, with other fascicles, into the thalamic nuclei, particularly the ventral anterior, ventral lateral and centromedian nuclei.

The thalamic fasciculus extends from the prerubral field, and its territory is termed the $H_1$ field of Forel. It lies dorsal to, and also partly traverses, the zona incerta, and is related dorsally to the ventral thalamic nuclei. It contains continuations of the fasciculus lenticularis and ansa lenticularis, and
dentatothalamic, rubrothalamic and thalamostriate fibres.

The subthalamic fasciculus connects the subthalamic nucleus with the globus pallidus. It contains an abundant two-way array of fibres which traverse the internal capsule, interweaving with it at right angles.
EPITHALAMUS

The epithalamus consists of the anterior and posterior paraventricular nuclei, the medial and lateral habenular nuclei, the stria medullaris thalami, posterior commissure and the pineal body.

HABENULAR NUCLEI AND STRIA MEDULLARIS

The habenular nuclei lie posteriorly at the dorsomedial aspect of the thalamus, immediately deep to the ependyma of the third ventricle, with the stria medullaris thalami above and laterally. The medial habenular nucleus is a densely packed, deeply staining, mass of cholinergic neurones, whereas the lateral nucleus is more dispersed and paler staining. The habenulo-interpeduncular tract, or fasciculus retroflexus, emerges from the ventral margin of the nuclei and courses ventrally, skirts the inferior zone of the thalamic mediodorsal nucleus, and traverses the superomedial region of the red nucleus to reach the interpeduncular nucleus. The habenular nuclear complex is limited laterally by a fibrous lamina, which enters the habenulo-interpeduncular tract. Posteriorly, the nuclei of the two sides and the internal medullary laminae are linked across the midline by the habenular commissure. The tela choroidea of the third ventricle usually arises from the ependyma at the superolateral corner of the medial habenular nucleus.

Afferent fibres to the habenular nuclei travel in the stria medullaris from the prepiriform cortex bilaterally, the basal nucleus of Meynert, and the hypothalamus. Afferents from the internal segment of the globus pallidus ascend through the thalamus, and may be collaterals of pallidothalamic axons. Additional inputs come from the pars compacta of the substantia nigra, the midbrain raphe nuclei and the lateral dorsal tegmental nucleus. The afferent pathways mostly end in the lateral habenular nucleus. The only identified afferent fibres to the medial habenular nucleus come from the septofimbrial nucleus.

The medial habenular nucleus sends efferent fibres to the interpeduncular nucleus of the midbrain. The lateral habenular nucleus sends fibres to the raphe nuclei and the adjacent reticular formation of the midbrain, the pars compacta of the substantia nigra and the ventral tegmental area, and to the hypothalamus and basal forebrain.

The main habenular outflow reaches the interpeduncular nucleus, mediodorsal thalamic nucleus, mesencephalic tectum and reticular formation, the largest component constituting the habenulo-interpeduncular tract to the interpeduncular nucleus. The latter provides relays to the midbrain reticular formation, from which tectotegmentospinal tracts and dorsal longitudinal fasciculi connect with autonomic preganglionic neurones controlling salivation, gastric and intestinal secretory activity and motility, and motor
the nuclei for mastication and deglutition.

The stria medullaris crosses the superomedial thalamic aspect, skirts medial to the habenular trigone and sends many fibres into the ipsi-lateral habenula. Other fibres cross in the anterior pineal lamina, and decussate, as the habenular commissure, to reach the contralateral habenula. Some fibres are really commissural and interconnect the amygdaloid complexes and hippocampal cortices. They are accompanied by crossed tectohabenular fibres. Serotonin-containing fibres from the ventral ascending tegmental serotonergic bundle, which join the habenulo-interpeduncular tract to reach the nuclei, may control neurones of the habenulopineal tract, and thus influence innervation of pinealocytes. Similarly, habenular nuclear afferents from the dorsal ascending tegmental noradrenergic bundle may influence pinealocytes.

Little is known of the physiological functions of the habenular nuclei. It has been suggested that they may be involved in the control of sleep mechanisms. Though the human habenula is relatively small, it is a focus of integration of diverse olfactory, visceral and somatic afferent paths. Lesions that include this area of the medial diencephalon indicate that it plays a role in the regulation of visceral and neuroendocrine functions. Ablation of the habenula causes extensive changes in metabolism, and endocrine and thermal regulation.
POSTERIOR COMMISSURE

The posterior commissure, which is of unknown constitution in man, is a small fasciculus that decussates in the inferior pineal lamina. Various small nuclei are associated with it. Among these are the interstitial nuclei of the posterior commissure, the nucleus of Darkschewitscz in the periaqueductal grey matter, and the interstitial nucleus of Cajal near the upper end of the oculomotor complex, closely linked with the medial longitudinal fasciculus. Fibres from all these nuclei and the fasciculus cross in the posterior commissure. It also contains fibres from thalamic and pretectal nuclei and the superior colliculi, together with fibres that connect the tectal and habenular nuclei. The destinations and functions of many of these fibres are obscure.
The pineal gland or epiphysis cerebri (see Figs 16.7, 19.3) is a small, reddish-grey organ, occupying a depression between the superior colliculi. It is inferior to the splenium of the corpus callosum, from which it is separated by the tela choroidea of the third ventricle and the contained cerebral veins. It is enveloped by the lower layer of the tela, which is reflected from the gland to the tectum. The pineal is about 8 mm long. Its base, directed anteriorly, is attached by a peduncle, which divides into inferior and superior laminae, separated by the pineal recess of the third ventricle, and containing the posterior and habenular commissures respectively. Aberrant commissural fibres may invade the gland but do not terminate near parenchymal cells.

Septa extend into the pineal gland from the surrounding pia mater. They divide the gland into lobules and carry blood vessels and fine unmyelinated sympathetic axons. The gland has a rich blood supply. The pineal arteries are branches of the medial posterior choroidal arteries, which are themselves branches of the posterior cerebral artery. Within the gland, branches of the arteries supply fenestrated capillaries whose endothelial cells rest on a tenuous and sometimes incomplete basal lamina. The capillaries drain into numerous pineal veins, which open into the internal cerebral veins and/or into the great cerebral vein.

Postganglionic adrenergic sympathetic axons (derived from neurones in the superior cervical ganglion) enter the dorsolateral aspect of the gland from the region of the tentorium cerebelli as the nervus conarii, which may be single or paired. The nerve lies deep to the endothelium of the wall of the straight sinus and is associated with blood vessels and parenchymal cells within the pineal.

The pineal gland contains cords and clusters of pinealocytes, associated with astrocyte-like neuroglia. Neuroglia are the main cellular component of the pineal stalk. Pinealocytes are highly modified neurones. They contain multiple synaptic ribbons, randomly distributed between adjacent cells, and are coupled by gap junctions. Two or more processes extend from each cell body and end in bulbous expansions near capillaries or, less frequently, on ependymal cells of the pineal recess. These terminal expansions contain rough endoplasmic reticulum, mitochondria and dense-cored vesicles which store melatonin. Melatonin, and its precursor serotonin, are synthesized from tryptophan by the pinealocytes, and secreted into the surrounding network of fenestrated capillaries.

The pineal is an endocrine gland of major regulatory importance. It modifies the activity of the adenohypophysis, neurohypophysis, endocrine pancreas, parathyroids, adrenal cortex, adrenal medulla and gonads. Its effects are largely inhibitory. Indoleamine and polypeptide hormones secreted by pinealocytes are believed to reduce the synthesis and release of hormones by the pars anterior, either by direct action on its secretory cells or indirectly by inhibiting production of hypothalamic releasing factors. Pineal secretions may reach their target cells via the cerebrospinal fluid or the bloodstream. Some pineal indoleamines, including melatonin and enzymes for their biosynthesis (e.g. serotonin N-acetyltransferase) show circadian rhythms in concentration. The level rises during darkness, and falls during the day, when secretion may be inhibited by sympathetic activity. It is thought that the intrinsic rhythmicity of an endogenous circadian oscillator in the suprachiasmatic nucleus of the hypothalamus governs cyclical pineal behaviour (see above).
From the second decade, calcareous deposits accumulate in pineal extracellular matrix, where they are deposited concentrically as corpora arenacea or ‘brain sand’ (Fig. 21.13). Calcification is often detectable in skull radiographs, when it can provide a useful indicator of a space-occupying lesion if the gland is significantly displaced from the midline.

CHAPTER 22 – Basal ganglia

The term basal ganglia is used to denote a number of subcortical nuclear masses that lie in the inferior part of the cerebral hemisphere, in close relation with the internal capsule (Figs 22.1, 22.2; see Fig. 23.28). The traditional definition of the basal ganglia included the corpus striatum, claustrum, and amygdaloid complex. The term has now been restricted to the corpus striatum and its associated structures in the diencephalon and midbrain; collectively they form a functional complex involved in the control of movement and motivational aspects of behaviour. The function of the claustrum is unknown; the amygdala is more closely related to the limbic system and is therefore described in that context (see Ch. 23).

The corpus striatum consists of the caudate nucleus, putamen and globus pallidus (Fig. 22.3). Because of their close proximity, the putamen and globus pallidus were once considered as an entity, termed the lentiform (lenticular) complex or nucleus. However, although the name has been retained in gross anatomical terminology and in some compound names (e.g. sublenticular, retrolenticular), it is now known that the putamen and caudate nucleus share a common chemocytarchitecture and connections, and they are referred to jointly as the neostriatum or simply the striatum.

The striatum is considered to be the principal ‘input’ structure of the basal ganglia since it receives the majority of afferents from other parts of the neuraxis. Its principal efferent connections are to the globus pallidus and pars reticulata of the substantia nigra. The globus pallidus and, more particularly, its medial segment, together with the pars reticulata of the substantia nigra is regarded as the main ‘output’ structure because it is the source of basal ganglia efferent fibre projections, mostly directed to the thalamus.

Disorders of the basal ganglia are principally characterized by abnormalities of movement, muscle tone and posture. There is a wide spectrum of clinical presentations ranging from poverty of movement and hypertonia at one extreme (typified by Parkinson’s disease) to abnormal involuntary movements (dyskinesias) at the other. The underlying pathophysiological mechanisms that mediate these disorders have been much studied in recent years and are better understood than for any other type of complex neurological dysfunction. This has led to the introduction of new rational therapeutic strategies for both medical and neurosurgical treatment of movement disorders.

The caudate nucleus is a curved, tadpole-shaped mass. It has a large anterior head, which tapers to a body, and a down-curving tail (Fig. 22.4). The head is covered with ependyma and lies in the floor and lateral wall of the anterior horn of the lateral ventricle, in front of the interventricular foramen. The tapering body is in the floor of the body of the ventricle, and the narrow tail follows the curve of the inferior horn, and so lies in the ventricular roof, in the temporal lobe. Medially, the greater part of the caudate nucleus abuts the thalamus, along a junction that is marked by a groove, the sulcus terminalis. The sulcus contains the stria terminalis, lying deep to the ependyma (Fig. 22.5). The sulcus terminalis is especially prominent anterosuperiorly (because of the large size of the head and body of the caudate nucleus relative to the tail), and here the stria terminalis is accompanied by the thalamostriate vein.

The corpus callosum lies above the head and body of the caudate nucleus. The two
are separated laterally by the fronto-occipital fasciculus, and medially by the subcallosal fasciculus which caps the nucleus (Figs 22.5, 22.6). The caudate nucleus is largely separated from the lentiform complex by the anterior limb of the internal capsule (Figs 22.1, 22.6 and 22.7). However, the inferior part of the head of the caudate becomes continuous with the most inferior part of the putamen immediately above the anterior perforated substance; this junctional region is sometimes known as the fundus striati (Fig. 22.6). Variable bridges of cells connect the putamen to the caudate nucleus for most of its length. They are most prominent anteriorly, in the region of the fundus striati and the head and body of the caudate nucleus, where they break up the anterior limb of the internal capsule (Fig. 22.7). In the temporal lobe, the anterior part of the tail of the caudate nucleus becomes continuous with the posteroinferior part of the putamen. The vast bulk of the caudate nucleus and putamen are often referred to as the dorsal striatum. A smaller inferomedial part of the rostral striatum is referred to as the ventral striatum, and includes the nucleus accumbens.

The lentiform complex (Figs 22.1, 22.2, 22.8) lies deep to the insular cortex, with which it is roughly coextensive, although they are separated by a thin layer of white matter and by the claustrum. The latter splits the insular subcortical white matter to create the extreme and external capsules; the external capsule separates the claustrum from the putamen. The internal capsule separates the lentiform complex from the caudate nucleus.

The lentiform complex consists of the laterally placed putamen and the more medial globus pallidus (pallidum), which are separated by a thin layer of fibres, the lateral or external medullary lamina. The globus pallidus is itself divided into two segments, a lateral (or external) segment and a medial (or internal) segment, separated by an internal (or medial) medullary lamina. The two segments have distinct afferent and efferent connections.

Inferiorly, a little behind the fundus striati, the lentiform complex is grooved by the anterior commissure, which connects inferior parts of the temporal lobes and the anterior olfactory cortex of the two sides (Fig. 22.6). The area above the commissure is referred to as the dorsal pallidum, and that below it as the ventral pallidum.

STRIATUM

The striatum consists of the caudate nucleus, putamen and ventral striatum, which are all highly cellular and well vascularized. The caudate and putamen are traversed by numerous small bundles of thinly-myelinated, or non-myelinated, small-diameter axons, which are mostly striatal afferents and efferents. They radiate through the striatal tissue as though converging on, or radiating from, the globus pallidus. The bundles are occasionally referred to by the archaic term ‘Wilson's pencils’ and they account for the striated appearance of the corpus striatum.

Neurones of both dorsal and ventral striatum are mainly medium-sized multipolar cells. They have round, triangular or fusiform somata, mixed with a smaller number of large multipolar cells. The ratio of medium to large cells is at least 20 : 1. The large neurones have extensive spherical or ovoid dendritic trees up to 60 µm across. The medium-sized neurones also have spherical dendritic trees, approximately 20 µm across, which receive the synaptic terminals of many striatal afferents. The dendrites of both medium and large striatal cells may be either spiny or non-spiny. The most common neurone (usually 75% of the total) is a medium-sized cell with spiny dendrites. These cells utilize γ-aminobutyric acid (GABA) as their transmitter and also express the genes coding for either enkephalin or substance P/dynorphin. Enkephalinergic neurones express D2 dopamine receptors. Substance P/dynorphin neurones express D1 receptors. These neurones are the major, and perhaps exclusive, source of striatal efferents to the pallidum and substantia nigra pars reticulata. The remaining medium-sized striatal neurones are aspiny, and are intrinsic cells that contain acetylcholinesterase (AChE), choline acetyltransferase (CAT) and somatostatin. Large neurones with spiny dendrites contain AChE and CAT; most, perhaps all, are intrinsic neurones. Aspiny large neurones are all intrinsic neurones.

Intrinsic synapses are probably largely asymmetric (type II), while those derived from external sources are symmetric (type I). The aminergic afferents from the substantia nigra, raphe and locus coeruleus all end as profusely branching axons with varicosities, which contain dense-core vesicles (the presumed store of amine transmitters). Many of these varicosities have no conventional synaptic membrane specializations, and may release transmitter in a way analogous to that found in peripheral postsynaptic sympathetic axons.

Neuroactive chemicals, whether intrinsic or derived from afferents, are not distributed uniformly in the striatum. For example, serotonin and glutamic acid decarboxylase (GAD) concentrations are highest caudally, while substance P, acetylcholine (ACh) and dopamine are highest rostrally. However, there is a finer grain neurochemical organization that informs the view of the striatum as a mosaic of islands or striosomes.
(sometimes referred to as patches), each 0.5–1.5 mm across, packed into a background matrix. Striosomes contain substance P and enkephalin. During development, the first dopamine terminals from the substantia nigra are found in striosomes. Although this exclusivity does not persist after birth, striosomes in the adult caudate nucleus still contain a higher concentration of dopamine than the matrix. The latter contains ACh and somatostatin and is the target of thalamostriate axons. Receptors for at least some neurotransmitters are also differentially distributed. For example, opiate receptors are found almost exclusively within striosomes, and muscarinic receptors predominantly so. Moreover, the distribution of neuroactive substances within the striosomes is not uniform. In humans, the striosome/matrix patchwork is less evident in the putamen, where it appears to consist predominantly of matrix, than it is in the caudate nucleus.

All afferents to the striatum terminate in a mosaic manner. The size of a cluster of terminals is usually 100–200 µm across. Some afferent terminal clusters are not arranged in register with the clear striosome/matrix distributions seen in nigrostriatal and thalamostriatal axons. In general, afferents from neocortex end in striatal matrix and those from allocortex end in striosomes. However, the distinction is not absolute: although afferents from the neocortex arise in layers V and VI, those from the superficial part of layer V end predominantly in striatal matrix, whereas those from deeper neocortex project to striosomes. Striatal cell bodies, which are the sources of efferents, also form clusters, but again are not uniformly related to striosomes. For example, the cell bodies of some striatopallidal and striatonigral axons lie clustered within striosomes, and others lie outside them, but still in clusters. The neurones and neuropil of the ventral striatum are essentially similar to those of the dorsal striatum, but the striosomal/matrix organization is less well-defined, and seems to consist predominantly of striosomes.

The major connections of the striatum are summarized in Fig. 22.9. Although the connections of the dorsal and ventral divisions overlap, the generalization can be made that the dorsal striatum is predominantly connected with motor and associative areas of the cerebral cortex, whilst the ventral striatum is connected with the limbic system and orbitofrontal and temporal cortices. For both dorsal and ventral striatum, the pallidum and substantia nigra pars reticulata are key efferent structures. The fundamental arrangement is the same for both divisions. The cerebral cortex projects to the striatum, which in turn projects to the pallidum and substantia nigra pars reticulata, and efferents from the pallidum and substantia nigra pars reticulata influence the cerebral cortex (either the supplementary motor area or prefrontal and cingulate cortices via the thalamus) and the superior colliculus (see below).
Fig. 22.9 Connections of the striatum. The major afferent projections to the striatum are shown on the right and major efferent projections from the striatum on the left.

The entire neocortex sends glutamatergic axons to the ipsilateral striatum. Previously, these axons were thought to be collaterals of cortical efferents to other regions, but it is now known that they arise exclusively from small pyramidal cells in layers V and VI. It has also been suggested that some of the cells of origin lie in the supragranular ‘cortical association’ layers II and III. The projection is organized topographically. The greater part of the input from the cerebral cortex to the dorsal striatum is derived from the frontal and parietal lobes, that from the occipitotemporal cortex being relatively small. Thus, the orbitofrontal association cortex projects to the inferior part of the head of the caudate nucleus, which lies next to the ventral striatum. The dorsolateral frontal association cortex and frontal eye fields project to the rest of the head of the caudate nucleus, and much of the parietal lobe projects to the body of the nucleus. The somatosensory and motor cortices project predominantly to the putamen. Their
afferents establish a somatotopic pattern, in which the lower body is represented laterally and the upper body is represented medially. The motor cortex is unique in sending axons through the corpus callosum to the opposite putamen, where they end with the same spatial ordering. The occipital and temporal cortices project to the tail of the caudate nucleus and to the inferior putamen.

The striatum also receives afferents, which are more crudely spatially organized, from the polysensory intralaminar thalamus. The cerebellomotor cortex centralis lateralis projects to the anterior striatum (especially the caudate nucleus), and the cerebellomotor and pallidoreceptive centromedian nucleus projects to the putamen.

The aminergic inputs to the caudate and putamen are derived from the substantia nigra pars compacta (dopaminergic group A9; Fig. 22.10), the retrorubral nucleus (dopaminergic group A8), the dorsal raphe nucleus (serotonergic group B7; Fig. 22.10) and the locus coeruleus (noradrenergic group A6). The nigrostriatal input is sometimes referred to as the ‘mesostriatal’ dopamine pathway. It reaches the striatum by traversing the H fields (of Forel) in the subthalamus and running in the median forebrain bundle. These aminergic inputs appear to modulate the responses of the striatum to cortical and thalamic afferent influences.
Efferents from the striatum pass to both segments of the globus pallidus and to the substantia nigra pars reticulata, where they end in a topically ordered fashion. Fibres ending in either the lateral or medial pallidal segment originate from different striatal cells (Fig. 22.9). Those to the lateral pallidum come from neurones which co-localize GABA and enkephalin and give rise to the so-called ‘indirect pathway’. This name refers to the fact that these striatal neurones influence the activity of basal ganglia output neurones in the medial pallidum via the intermediary of the subthalamic nucleus. Other striatal neurones, which co-localize GABA and substance P/dynorphin, project directly to the medial pallidum and are therefore described as the ‘direct pathway’.

A second outflow is established from the striatum to the pars reticulata of the substantia nigra. This also has both direct and indirect components, via the lateral pallidum and subthalamic nucleus (Figs 22.11, 22.12). The axons of the direct striatonigral projection constitute the laterally placed ‘comb’ system, which is spatially quite distinct from the ascending dopaminergic nigrostriatal pathway. Striatonigral fibres end in a spatially ordered way in the pars reticulata.
Fig. 22.11 The principal output connections of the basal ganglia derived from dorsal (A) and ventral (B) divisions of the striatum. In each case pathways established through the pallidum are distinguished from those passing through the substantia nigra pars reticulata. DA, dopamine; NA, noradrenaline (norepinephrine); 5HT, 5-hydroxytryptamine.

Fig. 22.12 The principal connections of the basal ganglia with the diencephalon and brain stem.
The ventral striatum is the primary target of cortical afferents from limbic cortices, including allocortex, and from limbic associated regions (Fig. 22.11). Thus, the hippocampus (through the fornix) and orbitofrontal cortex (through the internal capsule) project to the nucleus accumbens, and the olfactory, entorhinal, anterior cingulate and temporal visual cortices project to both the nucleus accumbens and olfactory tubercle in varying degrees. The tubercle also receives afferents from the amygdala. The contiguities of the cortical areas, which project to the ventral striatum and neighbouring dorsal striatum, emphasize the imprecise nature of the boundaries between the two divisions. All the cortical regions overlap and abut one another, and they project to neighbouring parts of the dorsal striatum as well as to the ventral striatum. The fundus striati and ventromedial caudate nucleus abut the olfactory tubercle and nucleus accumbens (Fig. 22.6), and receive connections from the orbitofrontal cortex and, to a lesser extent, from the lateral prefrontal and anterior cingulate cortices (which also project to the contiguous head of the caudate nucleus).

This continuity of the ventral and dorsal striata, as revealed by the arrangements of corticostriate projections, is reinforced by consideration of the aminergic inputs to the ventral striatum. They are derived from the dorsal raphe (serotonergic group B7), the locus coeruleus (noradrenergic group A6) and from the paranigral nucleus (dopamine group A10), as well as the most medial part of the substantia nigra pars compacta (A9) (Fig. 22.10). The dopamine projections constitute the so-called mesolimbic dopamine pathway, which also projects to the septal nuclei, hippocampus and amygdala and prefrontal and cingulate cortices through the medial forebrain bundle. The lateromedial continuity of cell groups A9 and 10 is thus reflected in the relative positions of their ascending fibres in the subthalamus and hypothalamus (the H fields and median forebrain bundle, respectively), as well as in the lateromedial topography of the dorsal and ventral striata (Fig. 22.6), which in turn have contiguous and overlapping sources of cortical afferents.

As with the dorsal striatum, efferents from the ventral striatum project to the pallidum (in this case the ventral pallidum) and the substantia nigra pars reticulata (Figs 22.11, 22.12). In the latter case, the connection is both direct and indirect via the subthalamic nucleus. The projections from the pars reticulata are as described for the dorsal system, but axons from the ventral pallidum reach the thalamic mediodorsal nucleus (which projects to cingulate and prefrontal association cortex) and midline nuclei (which project to the hippocampus). Ventral pallidal axons also reach the habenular complex of the limbic system.

The brain areas beyond the basal nuclei, substantia nigra and subthalamic nucleus, to which both ventral and dorsal systems appear to project, are, therefore, the prefrontal association and cingulate cortices and the deep superior colliculus.

Nucleus accumbens

The ventral striatum consists of the nucleus accumbens and the olfactory tubercle. In front of the anterior commissure, much of the grey matter of the anterior perforated substance, and especially the olfactory tubercle, is indistinguishable from, and continuous with, the fundus striati, in terms of cellular composition, histochemistry and interconnections. The caudate nucleus is continuous medially with the nucleus accumbens (Fig. 22.6), which abuts the nuclei of the septum, close by the paraolfactory area, diagonal band of Broca and the fornix.
The nucleus accumbens receives a dopaminergic innervation from the midbrain ventral tegmental area (cell group A10). It is believed to represent the neural substrate for the rewarding effects of several classes of drugs of abuse and is, therefore, a major determinant of their addictive potential. The experimental observation that the locomotor activating effects of psychomotor stimulant drugs such as amphetamine and cocaine (which act presynaptically on dopaminergic neurones to enhance dopamine release or block its reuptake, respectively) are dependent on dopamine transmission in the nucleus accumbens, led to the hypothesis that the reinforcing or rewarding properties of these drugs are mediated by the mesolimbic dopamine system.
GLOBUS PALLIDUS

The globus pallidus (pallidum) lies medial to the putamen and lateral to the internal capsule. It consists of two segments, lateral (external) and medial (internal), which are separated by an internal medullary lamina, and which have substantially different connections. Both segments receive large numbers of fibres from the striatum and subthalamic nucleus. The lateral segment projects reciprocally to the subthalamic nucleus as part of the ‘indirect pathway’. The medial segment is considered to be a homologue of the pars reticulata of the substantia nigra, with which it shares similar cellular and connectional properties. Together, these segments constitute the main output of the basal ganglia to other levels of the neuraxis, principally to the thalamus and superior colliculus.

The cell density of the globus pallidus is less than one-twentieth of that of the striatum. The morphology of the majority of cells is identical in the two segments. They are large multipolar GABAergic neurones that closely resemble those of the substantia nigra pars reticulata. The dendritic fields are discoid, with planes at right angles to incoming striatopallidal axons, each of which, therefore, potentially contacts many pallidal dendrites en passant. This arrangement, coupled with the diameters of the dendritic fields (500 µm), suggests that a precise topographical organization is unlikely within the pallidum.

Striatopallidal fibres are of two main types. They project either to the lateral or the medial pallidal segment. Those projecting to the lateral segment constitute the beginning of the so-called ‘indirect pathway’. They utilize GABA as their primary transmitter and also contain enkephalin. Efferent axons from neurones in the lateral segment pass through the internal capsule in the subthalamic fasciculus, and travel to the subthalamic nucleus (Fig. 22.13).
Striatopallidal axons destined for the medial pallidum constitute the so-called ‘direct pathway’. Like the indirect projection, these also utilize GABA as their primary transmitter but they also contain substance P and dynorphin, rather than enkephalin. Efferent axons from the medial pallidal segment project through the ansa lenticularis and fasciculus lenticularis (Fig. 22.13). The former runs round the anterior border of the internal capsule and the latter penetrates the capsule directly. Having traversed the internal capsule, both pathways unite in the subthalamic region, where they follow a horizontal hairpin trajectory, and turn upwards to enter the thalamus as the thalamic fasciculus. The trajectory circumnavigates the zona incerta and creates the so-called ‘H’ fields of Forel (Figs 22.5, 22.13). Within the thalamus, pallidothalamic fibres end in the ventral anterior and ventral lateral nuclei and in the intralaminar centromedian nucleus. These in turn project excitatory (presumed glutamatergic) fibres primarily to the frontal cortex, including the primary and supplementary motor areas. The medial pallidum also projects fibres caudally to the pedunculopontine nucleus (Fig. 22.12). This lies at the junction of the midbrain and the pons, close to the superior cerebellar peduncle, and corresponds approximately to the physiologically identified ‘mesencephalic locomotor region’.
SUBSTANTIA NIGRA

The substantia nigra is a nuclear complex deep to the crus cerebri in each cerebral peduncle of the midbrain. It consists of a pars compacta, pars reticulata and a smaller pars lateralis (Fig. 22.10). The pars compacta and pars lateralis correspond to the dopaminergic cell group A9. Together with the retrorubral nucleus (A8) they comprise most of the dopaminergic neurone population of the midbrain and are the source of the mesostriatal dopamine system that projects to the striatum. The pars compacta of each side is continuous with its contralateral counterpart through the ventral tegmental dopamine group A10, which is sometimes known as the paranigral nucleus. This is the source of the mesolimbic dopamine system, which supplies the ventral striatum and neighbouring parts of the dorsal striatum, and the prefrontal and anterior cingulate cortices. The dopaminergic neurones of the pars compacta (A9) and paranigral nucleus (ventral tegmental group A10) also contain cholecystokinin (CCK) or somatostatin.

The neurones of the pars reticulata and pallidum collectively constitute the output neurones of the basal ganglia system. The pars reticulata contains large multipolar cells, very similar to those of the pallidum: their disc-like dendritic trees, like those of the pallidum, are orientated at right angles to afferents from the striatum, probably making en-passant contacts. Like the striatopallidal axons, of which they may be collaterals, striatonigral axons utilize GABA and substance P or enkephalin. They distribute differentially in the pars reticulata, such that the enkephalinergic axons terminate in the medial part, whereas substance P axons terminate throughout.

The efferent neurones of the pars reticulata are GABAergic. They project to the deep (polysensory) layers of the superior colliculus and to the brain stem reticular formation, including the pedunculopontine nucleus. The pathway from the striatum to the superior colliculus, via the substantia nigra pars reticulata, is thought to function in the control of gaze in a manner analogous to the pathway that initiates general body movement via the pallidum, thalamus and supplementary motor cortex. The uncontrolled or fixed-gaze disturbances of advanced Parkinson's disease, progressive supranuclear palsy (PSP) and Huntington's disease tend to support this.
SUBTHALAMIC NUCLEUS

The subthalamic nucleus is a biconvex, lens-shaped nucleus in the subthalamus of the diencephalon. It lies medial to the internal capsule, immediately rostral to the level at which the latter becomes continuous with the crus cerebri of the midbrain (Figs 22.2, 22.5, 22.8). Within the nucleus, small interneurones intermingle with large multipolar cells with dendrites which extend for about one-tenth the diameter of the nucleus. The nucleus is encapsulated dorsally by axons, many of which are derived from the subthalamic fasciculus: they carry a major GABAergic projection from the lateral segment of the globus pallidus as part of the indirect pathway. It also receives afferents from the cerebral cortex. The subthalamic nucleus is unique in the intrinsic circuitry of the basal ganglia in that its cells are glutamatergic and project excitatory axons to both the globus pallidus and substantia nigra pars reticulata. Within the pallidum, subthalamic efferent fibres end predominantly in the medial segment but many also end in the lateral segment.

The subthalamic nucleus plays a central role in the normal function of the basal ganglia and in the pathophysiology of basal ganglia-related disorders. Destruction of the nucleus, which occurs rarely as a result of stroke, results in the appearance of violent, uncontrolled involuntary movements, known as ballism (ballismus). The subthalamic nucleus is also crucially involved in the pathophysiology of Parkinson's disease and is a target for functional neurosurgical therapy of the condition.
PATHOPHYSIOLOGY OF BASAL GANGLIA DISORDERS

The normal functions of the basal ganglia are difficult to summarize succinctly. As far as their role in movement control is concerned, a reasonable definition is that they function to promote and support patterns of behaviour and movement that are appropriate in the prevailing circumstances and to inhibit unwanted or inappropriate behaviour and movements. This is exemplified by disorders of the basal ganglia, which are characterized, depending on the underlying pathology, by an inability to initiate and execute wanted movements (as in Parkinson's disease) or an inability to prevent unwanted movements (as in Huntington's disease).

Parkinson's disease is the most common pathological condition affecting the basal ganglia. It is characterized by akinesia, muscular rigidity and tremor due to degeneration of the dopaminergic neurones of the substantia nigra pars compacta (which project to the striatum in the nigrostriatal pathway). As a consequence, dopamine terminals are lost in the striatum and dopamine levels are severely depleted. Dopamine receptors, which are located upon medium spiny neurones, and are the target of the nigrostriatal pathway, are spared.

Dopamine appears to have a dual action on medium spiny striatal neurones. It inhibits those of the indirect pathway and excites those of the direct pathway. Consequently, when dopamine is lost from the striatum, the indirect pathway becomes overactive and the direct pathway becomes underactive (Fig. 22.14). Overactivity of the striatal projection to the lateral pallidum results in inhibition of pallidosubthalamic neurones and, consequently, overactivity of the subthalamic nucleus. Subthalamic efferents mediate excessive excitatory drive to the medial globus pallidus and substantia nigra pars reticulata. This is exacerbated by underactivity of the GABAergic, inhibitory direct pathway. Overactivity of basal ganglia output then inhibits the motor thalamus and its excitatory thalamocortical connections. While this description is little more than a first approximation of the underlying pathophysiology, this model of the basis of parkinsonian symptoms has led to the introduction of new neurosurgical approaches to the treatment of Parkinson's disease, based upon lesioning and deep brain stimulation of the medial globus pallidus and subthalamic nucleus (see below).
The current medical treatment for Parkinson's disease relies upon levodopa (L-DOPA; L-dihydroxyphenylalanine), the immediate metabolic precursor of dopamine, or upon dopamine agonists. Whilst these usually provide good symptomatic relief for many years, eventually they lead to the development of side-effects, including dyskinesias. The involuntary movements that occur as a consequence of long-term treatment of Parkinson's disease resemble those seen in Huntington's disease, tardive dyskinesia and ballism. Experimental evidence suggests that these may share a common neural mechanism (Fig. 22.14). Thus, the indirect pathway becomes underactive, e.g. due to the effects of dopaminergic drugs in Parkinson's disease, or the degeneration of the striatopallidal projection to the lateral pallidum in Huntington's disease. This leads to physiological inhibition of the subthalamic nucleus by overactive pallidosubthalamic neurones. The involvement of the subthalamic nucleus explains why the dyskinetic movements of levodopa-induced dyskinesia and Huntington's disease resemble those of ballism produced by lesion of the subthalamic nucleus. Underactivity of the subthalamic nucleus removes the excitatory drive from medial pallidal neurones, which are known to be underactive in dyskinesias. Once again this is an oversimplification. Whilst it is true that underactivity of the medial globus pallidus is associated with dyskinesias, it is also known that lesions of the globus pallidus alleviate them. This suggests that the dynamic aspects of pallidal and nigral efferent activity are important factors in the generation of dyskinesia.

Another manifestation of basal ganglia dysfunction is dystonia, which is characterized by increased muscle tone and abnormal postures. Dystonia may occur as a consequence of levodopa treatment in Parkinson's disease or inherited disease (e.g. early-onset torsion, or Oppenheim's dystonia, an autosomal dominant disorder most commonly associated with a mutation in the \(\text{DYT1} \) gene that encodes torsinA). The
pathophysiological basis of dystonia is unclear. Like dyskinesias it is probably caused by underactivity of basal ganglia output, and so deep-brain stimulation of the globus pallidus may be beneficial.

There is evidence that dysfunction of the basal ganglia is involved in other complex, less well-understood, behavioural disorders. In animal experiments, lesions of the basal ganglia, especially of the caudate nucleus, induce uncontrollable hyperactivity (e.g. obstinate pacing and other constantly repeated behaviours). This and other evidence has led to the notion that the corpus striatum enables the individual to make motor choices and to avoid ‘stimulus-bound’ behaviour. PET scanning studies in man have shown that sufferers from obsessive-compulsive disorder (OCD), which is characterized by repeated ritualistic motor behaviour and intrusive thoughts, exhibit abnormal activity in the prefrontal cortex and caudate nuclei. There are similar suggestive observations in the hyperactive child syndrome. In this respect it may be significant that the basal ganglia, besides receiving connections from the frontal lobe and limbic cortices, also have an ascending influence on the prefrontal and cingulate cortices through the substantia nigra pars reticulata and dorsomedial and ventromedial thalamus (Fig. 22.11).

Before the advent of levodopa therapy, neurosurgery for Parkinson's disease was commonplace. The globus pallidus and thalamus were favoured targets for chemical or thermal lesions. Pallidotomy and thalamotomy often improved rigidity and tremor, but they produced little consistent beneficial effect upon akinesia. With the arrival of levodopa therapy, which has a profound effect upon akinesia, the surgical treatment of Parkinson's disease underwent progressive decline. However, it soon became clear that long-term use of levodopa was associated with a number of side-effects such as dyskinesias, ‘wearing-off’, and the ‘on–off’ phenomenon. More recent advances in understanding the pathophysiology of movement disorders, and in particular Parkinson's disease, have stimulated a renaissance in the use of neurosurgery to treat movement disorders.

Lesioning the subthalamic nucleus in experimental primates that had been made parkinsonian with the neurotoxin MPTP dramatically alleviated the parkinsonian symptoms, suggesting that the subthalamic nucleus might be an appropriate clinical target. While therapeutic surgical lesions of the subthalamic nucleus can alleviate tremor, rigidity and bradykinesia in patients with Parkinson's disease, the risk of side-effects is not trivial: the subthalamic nucleus is a small structure wrapped by fibres of passage and close to the hypothalamus and internal capsule. Perhaps not surprisingly, relatively few centres perform this procedure.

In 1992, Laitinen et al reintroduced pallidotomy for the treatment of end-stage Parkinson's disease, but confined the lesions to the posteroventral part of the medial pallidal segment. These lesions were found to be extremely reliable in abolishing contralateral rigidity and drug-induced dyskinesias, with slightly less efficacy on tremor and bradykinesia.

Implantation of deep-brain electrodes through which high-frequency pulses generated by a pacemaker could inhibit cells in the vicinity has been a concept since the early 1970s, but did not become a widespread reality until the late 1980s, as a result of technological advances. The introduction of the technique of deep brain stimulation (DBS), which avoids making permanent lesions, made bilateral surgery safer. There
have been numerous reports of the effectiveness of both bilateral pallidal and subthalamic nucleus stimulation (Figs 22.15, 22.16). Subthalamic nucleus stimulation is favoured by most groups because, unlike pallidal stimulation, it allows patients to reduce their anti-parkinsonian medication.

**Fig. 22.15** MRI image showing placement of deep brain stimulating electrodes bilaterally in the globus pallidus of a patient with Parkinson’s disease.
Serendipity also has a role in such surgery. Clinically, parkinsonian patients can develop painful dystonic posturing of their limbs which responds dramatically to bilateral pallidal stimulation. This has led to preliminary studies of bilateral pallidal stimulation for dystonia with very promising results. Since it is held that in dystonia the pallidal neurones fire at rates below normal, this presents quite a puzzle as it is open...
to question how stimulation works. It also would appear that the neural mechanism that underlies this therapeutic effect on dystonia may differ from that in Parkinson's disease and tremor, because in dystonia the improvement may take weeks to emerge, whereas it is immediate in the case of Parkinson's disease.

An even more recent neurosurgical development in the therapy of Parkinson's disease has involved targeting the pedunculopontine nucleus (nucleus tegmenti pedunculopontinus; PPN). The PPN corresponds approximately to the so-called 'mesencephalic locomotor region': stimulation of this region in animals elicits locomotion. The PPN is maximal at the boundary between midbrain and pons, and is bounded laterally by the medial leminiscus and medially by the superior cerebellar peduncle and its decussation. Dorsally it is bounded by the pontine cuneiform and subcuneiform nuclei and ventrally by the pontine reticular formation. Its most caudal pole is adjacent to the locus coeruleus.

The PPN has a caudal pars compacta that consists largely of cholinergic neurones and a rostral pars dissipata that consists largely of glutamatergic neurones. It is known to receive GABAergic efferent fibres from the globus pallidus and substantia nigra. In animal models of Parkinson's disease these projections are overactive and the PPN is inhibited. Taken in conjunction with other experimental evidence, this suggests the possibility that the PPN is involved in the pathophysiology of disturbances of locomotion, gait and posture in Parkinson's disease. Recently, DBS of PPN through implanted electrodes has been applied in drug-resistant akinetic parkinsonian patients (Fig. 22.17). Low frequency stimulation alleviates postural instability and on-medications gait freezing, symptoms which conventional medication and surgery fail to improve.

CHAPTER 23 – Cerebral hemisphere

The two cerebral hemispheres are the largest major divisions of the brain. Each hemisphere consists of an external highly-convoluted cortex, beneath which lies an extensive internal mass of white matter that partly encloses the basal ganglia. Each hemisphere also contains a lateral ventricle that is continuous with the third ventricle through the interventricular foramen. The two hemispheres are linked by the commissural fibres of the corpus callosum.

The cerebral hemisphere contains primary motor and sensory cortical areas. These represent the highest level at which motor activities are controlled and the highest level to which general and special sensory systems project, providing the neural substrate for conscious experience of sensory stimuli. Association areas are modality-specific and also multimodal, and they enable complex analysis of the internal and external environment and the relationship of the individual to the external world. Parts of the hemisphere, termed the limbic system, have an ancient lineage. They are concerned with memory and the emotional aspects of behaviour, and provide an affective overtone to conscious experience as well as interfacing with subcortical areas, such as the hypothalamus, through which widespread physiological activities are integrated. Other cortical areas, primarily within the frontal region, are concerned with the highest aspects of cognitive function, and contribute to personality, foresight and planning.

The cerebral hemispheres are separated by a deep median cleft, the great longitudinal fissure, which contains a crescent-shaped fold of the dura mater, the falx cerebri (see Ch. 27).

Each cerebral hemisphere may be considered to have superolateral, medial and inferior (basal) surfaces or aspects. The superolateral surface follows the concavity of the cranial vault. The medial surface is flat and vertical, separated from the opposite hemisphere by the great longitudinal fissure and falx cerebri. The inferior surface is irregular and divided into orbital and tentorial regions. The orbital part is concave and lies above the orbital and nasal roofs. The tentorial part lies in the middle cranial fossa; posteriorly it lies above the tentorium cerebelli, which separates it from the superior surface of the cerebellum.

GYRI, SULCI AND LOBES

The surface of the cerebral hemisphere shows a complex pattern of convolutions, or gyri, which are separated by furrows of varying depth known as fissures, or sulci (Fig. 23.1, Fig. 23.2). Some of these are consistently located, others less so. They provide part of the basis for the division of the hemisphere into lobes. The frontal, parietal, temporal and occipital lobes approximately correspond in surface extent to the overlying cranial bones from which they take their names. The anterior and posterior extremities of the hemispheres form the frontal and occipital poles respectively, and the temporal pole is the anterior extremity of the temporal lobe.
Fig. 23.1 Lateral aspect of the left cerebral hemisphere indicating the major gyri and sulci. (Dissection by EL Rees; photograph by Kevin Fitzpatrick on behalf of GKT School of Medicine, London; figure enhanced by B. Crossman.)
The insula is a cortical region hidden within the depths of the lateral fissure by overhanging parts (opercula) of the frontal, parietal and temporal lobes. A complex of gyri on the medial aspect of the hemisphere makes up the limbic lobe.

The area of the adult cerebral cortex is approximately $2200 \text{ cm}^2$: its convoluted form increases the cortical volume to three times greater than it would be if the surface were smooth.

Two prominent furrows, the lateral (Sylvian) fissure and the central sulcus, are the main features on the superolateral cerebral surface, and they determine its surface divisions.

The lateral fissure is a deep cleft on the lateral and inferior surfaces. It separates the frontal and parietal lobes above from the temporal lobe below and accommodates the middle cerebral vessels. It commences inferiorly at the anterior perforated substance, extending laterally between the orbital surface of the frontal lobe and the anterior pole of the temporal lobe and accommodating the sphenoparietal venous sinus. Reaching the lateral surface of the hemisphere it gives rise to an ascending ramus which runs into the inferior frontal gyrus. The larger posterior ramus runs posteriorly and slightly upwards, across the lateral surface of the hemisphere to end in the parietal lobe. The insula lies in the depths of the lateral fissure.

The central sulcus is the boundary between the frontal and parietal lobes and demarcates the primary motor and somatosensory areas of the cortex, located in the precentral and postcentral gyri, respectively. It starts in or near the superomedial border of the hemisphere, a little behind the midpoint between the frontal and occipital poles. It runs sinuously downwards and forwards to end a little above the posterior ramus of the lateral sulcus.

The superior frontal gyrus, above the superior frontal sulcus, is continuous over the superomedial margin with the medial frontal gyrus and may be incompletely divided. The middle frontal gyrus lies between the superior and inferior frontal sulci. The inferior frontal gyrus lies below the inferior frontal sulcus which is invaded by the ascending ramus of the lateral fissure. In the left hemisphere, the cortical areas around this ramus make up the motor speech area (Broca's area; areas 44 and 45).

The medial cerebral surface lies within the great longitudinal fissure. The commissural fibres of the corpus callosum lie in the depths of the fissure: the curved anterior part of the corpus callosum, the genu, is continuous below with the rostrum and narrows...
rapidly as it passes back to the upper end of the lamina terminalis. The cortex immediately below the rostrum is the subcallosal area (parolfactory gyrus). The genu of the corpus callosum continues above into the trunk or body, which arches up and back to a thick, rounded posterior extremity, the splenium. The bilateral vertical laminae of the septum pellucidum are attached to the concave surfaces of the trunk, genu and rostrum, occupying the interval between them and the fornix.

The anterior region of the medial surface of the hemisphere is divided into outer and inner zones by the curved cingulate sulcus, which starts below the rostrum and passes first forwards, then up and finally backwards, conforming to the callosal curvature. Its posterior end turns up to the superomedial margin of the hemisphere approximately 4 cm behind its midpoint, and is posterior to the upper end of the central sulcus. The outer zone, except for its posterior extremity, is part of the frontal lobe, and is subdivided into anterior and posterior areas by a short sulcus, which ascends from the cingulate sulcus above the midpoint of the corpus callosum. The larger anterior area is the medial frontal gyrus; the posterior is the paracentral lobule. The superior end of the central sulcus usually invades the paracentral lobule posteriorly and the precentral gyrus is continuous with the lobule. This area is concerned with movements of the contralateral lower limb and perineal region – clinical evidence suggests that it exercises voluntary control over defaecation and micturition.

The zone under the cingulate sulcus is the cingulate gyrus. Starting below the rostrum, this gyrus follows the callosal curve, separated by the callosal sulcus. It continues round the splenium to the inferior surface, and then into the parahippocampal gyrus, through the narrow isthmus.

The posterior region of the medial surface is traversed by the parieto-occipital and the calcarine sulci. These two deep sulci converge anteriorly to meet a little posterior to the splenium. The parieto-occipital sulcus marks the boundary between parietal and occipital lobes. It starts on the superomediaal margin of the hemisphere approximately 5 cm anterior to the occipital pole, sloping down and slightly forwards to the calcarine sulcus. The calcarine sulcus starts near the occipital pole. Though usually restricted to the medial surface, its posterior end may reach the lateral surface. Directed anteriorly, it joins the parieto-occipital sulcus at an acute angle behind the splenium. Continuing forwards, it crosses the inferomediaal margin of the hemisphere, and forms the inferior boundary of the isthmus, which connects the cingulate with the parahippocampal gyrus. The visual cortex lies above and below the posterior part of the calcarine sulcus, behind the junction with the parieto-occipital. The calcarine sulcus is deep and produces an elevation, the calcar avis, in the wall of the posterior horn of the lateral ventricle.

The area posterior to the upturned end of the cingulate sulcus, and anterior to the parieto-occipital sulcus, is the precuneus. It forms the medial surface of the parietal lobe with the part of the paracentral lobule behind the central sulcus. The medial surface of the occipital lobe is formed by the cuneus, a wedge of cortex bounded in front by the parieto-occipital sulcus, below by the calcarine sulcus, and above by the superomediaal margin.

The inferior cerebral surface is divided by the stem of the lateral fissure into a small anterior and larger posterior part (Fig. 23.3, Fig. 23.4). The anterior part constitutes
the orbital region of the frontal lobe. It is concave and lies above the cribriform plate of the ethmoid, the orbital plate of the frontal, and the lesser wing of the sphenoid bone. A rostrocaudal olfactory sulcus traverses it near its medial margin, overlapped by the olfactory bulb and tract. The medial strip thus demarked is the gyrus rectus. The rest of this surface bears irregular orbital sulci, generally H-shaped, which divide it into the anterior, medial, posterior and lateral orbital gyri.

Fig. 23.3 Basal aspect of the brain.
The larger, posterior region of the inferior cerebral surface is partly superior to the tentorium but also to the middle cranial fossa. The collateral sulcus starts near the occipital pole, and extends anteriorly and parallel to the calcarine sulcus, separated from it by the lingual gyrus. The lingual gyrus, between the calcarine and collateral sulci, passes into the parahippocampal gyrus, which begins at the isthmus where it is continuous with the cingulate gyrus. Anteriorly, the parahippocampal gyrus continues into the hook-shaped uncus, which lies lateral to the midbrain and posterolateral to the anterior perforated substance. The uncus is part of the piriform cortex of the olfactory system, phylogenetically one of the oldest parts of the cortex, and is separated from
the temporal pole by the rhinal sulcus (fissure) which marks the lateral limit of the entorhinal cortex (area) (Fig. 23.4).

The occipitotemporal sulcus is parallel and lateral to the collateral sulcus, does not usually reach the occipital pole, and is frequently divided. The medial occipitotemporal gyrus extends from the occipital to the temporal pole and is limited medially by the collateral and rhinal sulci and laterally by the occipitotemporal sulcus. The lateral occipitotemporal gyrus is continuous, round the inferolateral margin of the hemisphere, with the inferior temporal gyrus.
CEREBRAL CORTEX

The cerebral cortex is sometimes described as consisting of a phylogenetically old allocortex, which includes archicortex and palaeocortex, and a newer neocortex. These distinctions are reflected in the organizational arrangement of neuronal elements in different regions.

MICROSTRUCTURE

The microscopic structure of the cerebral cortex is an intricate blend of nerve cells and fibres, neuroglia and blood vessels. The neocortex essentially consists of three neuronal cell types. Pyramidal cells are the most abundant. Non-pyramidal cells, also called stellate or granule cells are divided into spiny and non-spiny neurones. All types have been subdivided on the basis of size and shape (Fig. 23.5).
Pyramidal cells have a flask-shaped or triangular cell body ranging from 10 to 80 µm in diameter. The soma gives rise to a single thick apical dendrite and multiple basal dendrites. The apical dendrite ascends towards the cortical surface, tapering and branching, to end in a spray of terminal twigs in the most superficial lamina, the molecular layer. From the basal surface of the cell body, dendrites spread more horizontally, for distances up to 1 mm for the largest pyramidal cells. Like the apical dendrite, the basal dendrites branch profusely along their length. All pyramidal cell dendrites are studded with a myriad of dendritic spines. These become more numerous as distance from the parent cell soma increases. A single slender axon arises from the axon hillock, which is usually situated centrally on the basal surface of the pyramidal neurone. Ultimately, in the vast majority of, if not in all, cases, the axon leaves the cortical grey matter to enter the white matter. Pyramidal cells are thus, perhaps universally, projection neurones. They use an excitatory amino acid, either glutamate or aspartate, as their neurotransmitter.

Spiny stellate cells are the second most numerous cell type in the neocortex and for
the most part occupy lamina IV. They have relatively small multipolar cell bodies, commonly 6 to 10 µm in diameter. Several primary dendrites, profusely covered in spines, radiate for variable distances from the cell body. Their axons ramify within the grey matter predominantly in the vertical plane. Spiny stellate cells probably use glutamate as their neurotransmitter.

The smallest group comprises the heterogeneous non-spiny or sparsely spinous stellate cells. All are interneurones, and their axons are confined to grey matter. In morphological terms, this is not a single class of cell, but a multitude of different forms, including basket, chandelier, double bouquet, neurogliaform, bipolar/fusiform and horizontal cells. Various types may have horizontally, vertically or radially ramifying axons.

Neurones with mainly horizontally dispersed axons include basket and horizontal cells. Basket cells have a short, vertical axon, which rapidly divides into horizontal collaterals, and these end in large terminal sprays synapsing with the somata and proximal dendrites of pyramidal cells. The cell bodies of horizontal cells lie mainly at the superficial border of lamina II, occasionally deep in lamina I (the molecular or plexiform layer). They are small and fusiform, and their dendrites spread short distances in two opposite directions in lamina I. Their axons often stem from a dendrite, then divide into two branches, which travel away from each other for great distances in the same layer.

Neurones with an axonal arborization predominantly perpendicular to the pial surface include chandelier, double bouquet and bipolar/fusiform cells. Chandelier cells have a variable morphology, although most are ovoid or fusiform and their dendrites arise from the upper and lower poles of the cell body. The axonal arborization, which emerges from the cell body or a proximal dendrite, is characteristic and identifies these neurones. A few cells in the more superficial laminae (II and IIIa) have descending axons, deeper cells (laminae IIIc and IV) have ascending axons, and intermediate neurones (IIIb) often have both. The axons ramify close to the parent cell body and terminate in numerous vertically oriented strings, which run alongside the axon hillocks of pyramidal cells with which they synapse. Double bouquet (or bitufted) cells are found in laminae II and III and their axons traverse laminae II and V. Generally, these neurones have two or three main dendrites, which give rise to a superficial and deep dendritic tuft. A single axon arises usually from the oval or spindle-shaped cell soma and rapidly divides into an ascending and descending branch. These branches collateralize extensively, but the axonal arbor is confined to a perpendicularly extended, but horizontally confined, cylinder, approximately 50 to 80 µm across. Bipolar cells are ovoid with a single ascending and a single descending dendrite, which arise from the upper and lower poles, respectively. These primary dendrites branch sparsely and their branches run vertically to produce a narrow dendritic tree, rarely more than 10 µm across, which may extend through most of the cortical thickness. Commonly, the axon originates from one of the primary dendrites, and rapidly branches to give a vertically elongated, horizontally confined, axonal arbor, which closely parallels the dendritic tree in extent.

The principal recognizable neuronal type is the neurogliaform or spiderweb cell. These small spherical cells, 10 to 12 µm in diameter, are found mainly in laminae II to IV, depending on cortical area. Seven to ten thin dendrites typically radiate out from the cell soma, some branching once or twice to form a spherical dendritic field of
approximately 100 to 150 µm diameter. The slender axon arises from the cell body or a proximal dendrite. Almost immediately, it branches profusely within the vicinity of the dendritic field (and usually somewhat beyond), to give a spherical axonal arbor up to 350 µm in diameter.

The majority of non-spiny or sparsely spinous non-pyramidal cells probably use GABA as their principal neurotransmitter. This is almost certainly the case for basket, chandelier, double bouquet, neurogliaform and bipolar cells. Some are also characterized by the coexistence of one or more neuropeptides, including neuropeptide Y, vasoactive intestinal polypeptide (VIP), cholecystokinin, somatostatin and substance P. Acetylcholine is present in a subpopulation of bipolar cells, which may additionally be GABAergic and contain VIP.

Laminar organization

The most apparent microscopical feature of the neocortex when it has been stained for cell bodies or for fibres is its horizontal lamination. The significance of this for understanding cortical functional organization is debatable, but the use of cytoarchitectonic description to identify regions of cortex is common.

Typical neocortex is described as having six layers or laminae lying parallel to the surface (Fig. 23.6).
Fig. 23.6 The layers of the cerebral cortex. The three vertical columns represent the disposition of cellular elements as revealed by the staining techniques of Golgi (impregnating whole neurones), Nissl (staining cell bodies) and Weigert (staining nerve fibres).

I The molecular or plexiform layer is cell sparse, containing only scattered horizontal cells and their processes enmeshed in a compacted mass of tangential, principally horizontal axons and dendrites. These are afferent fibres, which arise from outside the cortical area, together with intrinsic fibres from cortical interneurones, and the apical dendritic arbors of virtually all pyramidal neurones of the cerebral cortex. In histological sections stained to show myelin, layer I appears as a narrow horizontal band of fibres.

II The external granular lamina contains a varying density of small neuronal cell bodies including both small pyramidal and non-pyramidal cells; the latter may predominate. Myelin fibre stains show mainly vertically arranged processes traversing the layer.
The external pyramidal lamina contains pyramidal cells of varying sizes, together with scattered non-pyramidal neurones. The size of the pyramidal cells is smallest in the most superficial part of the layer and greatest in the deepest part. This lamina is frequently further subdivided into IIIa, IIIb and IIIc, with IIIa most superficial and IIIc deepest. As in layer II, myelin stains reveal a mostly vertical organization of fibres.

The internal granular lamina is usually the narrowest of the cellular laminae. It contains densely packed, small, round cell bodies of non-pyramidal cells, notably spiny-stellate cells and some small pyramidal cells. Within the lamina, in myelin stained sections, a prominent band of horizontal fibres (outer band of Baillarger) is seen.

The internal pyramidal (ganglionic) lamina typically contains the largest pyramidal cells in any cortical area, though actual sizes vary considerably from area to area. Scattered non-pyramidal cells are also present. In myelin stains, the lamina is traversed by ascending and descending vertical fibres, and also contains a prominent central band of horizontal fibres (inner band of Baillarger).

The multiform (or fusiform/pleiomorphic) layer consists of neurones with a variety of shapes, including recognizable pyramidal, spindle, ovoid and many other shaped somata. Typically, most cells are small to medium in size. This lamina blends gradually with the underlying white matter, and a clear demarcation of its deeper boundary is not always possible.

Five regional variations are described in neocortical structure (Fig. 23.7). While all are said to develop from the same six-layered pattern, two types, granular and agranular, are regarded as virtually lacking certain laminae, and are referred to as heterotypical. Homotypical variants, in which all six laminae are found, are called frontal, parietal and polar, names that link them with specific cortical regions in a somewhat misleading manner (e.g. the frontal type also occurs in parietal and temporal lobes).
The agranular type is considered to have diminished, or absent, granular laminae (II and IV), but always contains scattered stellate somata. Large pyramidal neurones are found in the greatest densities in agranular cortex, which is typified by the numerous efferent projections of pyramidal cell axons. Although it is often equated with motor cortical areas such as the precentral gyrus (area 4), agranular cortex also occurs elsewhere, e.g. areas 6, 8 and 44 and parts of the limbic system.

In the granular type of cortex the granular layers are maximally developed, and contain densely packed stellate cells, among which small pyramidal neurones are dispersed. Laminae III and IV are poorly developed or unidentifiable. This type of cortex is particularly associated with afferent projections. However, it does receive efferent fibres, derived from the scattered pyramidal cells, although they are less numerous than elsewhere. Granular cortex occurs in the postcentral gyrus (somatosensory area), striate area (visual area) and superior temporal gyrus (acoustic area), and in small areas of the parahippocampal gyrus. Despite its very high density of stellate cells, especially in the striate area, it is almost the thinnest of the five main types. In the striate cortex the external band of Baillarger (lamina IV) is well defined as the stria (white line) of Gennari.

The other three types of cortex are intermediate forms. In the frontal type, large numbers of small- and medium-sized pyramidal neurones appear in laminae III and V, and granular layers (II and IV) are less prominent. The relative prominence of these major forms of neurone vary reciprocally wherever this form of cortex exists.

The parietal type of cortex contains pyramidal cells, which are mostly smaller in size than in the frontal type. In marked contrast, the granular laminae are wider and contain more of the stellate cells: this kind of cortex occupies large areas in the parietal and temporal lobes. The polar type is classically identified with small areas near the frontal and occipital poles and is the thinnest form of cortex. All six laminae are represented, but the pyramidal layer (III) is reduced in thickness and not so extensively invaded by stellate cells as it is in the granular type of cortex. In both polar and granular types, the multiform layer (VI) is more highly organized than in other types.

It is customary to refer to some discrete cortical territories not only by their anatomical location in relation to gyri and sulci, but also in relation to their cytoarchitectonic characteristics (Brodmann's areas) (Fig. 23.8). Some of the areas so defined, e.g. the primary sensory and motor cortices, have clear relevance in terms of anatomical connections and functional significance, others less so.
Fig. 23.8  The lateral (A) and medial (B) surfaces of the left cerebral hemisphere depicting Brodmann's areas.
OVERVIEW OF CORTICAL CONNECTIVITY

All neocortical areas have axonal connections with other cortical areas on the same side (association fibres), the opposite side (commissural fibres), and with subcortical structures (projection fibres).

The primary somatosensory, visual and auditory areas give rise to ipsilateral corticocortical connections to the association areas of the parietal, occipital and temporal lobes, respectively, which then progressively project towards the medial temporal limbic areas, notably the parahippocampal gyrus, entorhinal cortex and hippocampus. Thus, the first (primary) somatic sensory area (SI) projects to the superior parietal cortex (Brodmann's area 5), which in turn projects to the inferior parietal cortex (area 7). From here connections pass to cortex in the walls of the superior temporal sulcus, and so on to the posterior parahippocampal gyrus, and on into limbic cortex. Similarly, for the visual system, the primary visual cortex (area 17) projects to the parastriate cortex (area 18), which in turn projects to the peristriate region (area 19). Information then flows to inferotemporal cortex (area 20), to cortex in the walls of the superior temporal sulcus, then to medial temporal cortex in the posterior parahippocampal gyrus, and so to limbic areas. The auditory system shows a similar progression from primary auditory cortex to temporal association cortex and so to the medial temporal lobe.

In addition to this stepwise outward progression from sensory areas through posterior association cortex, connections also occur at each stage with parts of the frontal cortex. Thus, taking the somatic sensory system as an example, primary somatic sensory cortex (SI) in the postcentral gyrus is reciprocally connected with the primary motor cortex (area 4) in the precentral gyrus. The next step in the outward progression, the superior parietal lobule (area 5), is interconnected with the premotor cortex (area 6), and this in turn is connected with area 7 in the inferior parietal lobe. This has reciprocal connections with prefrontal association cortex on the lateral surface of the hemisphere (areas 9 and 46), and temporal association areas, which connect with more anterior prefrontal association areas, and, ultimately in the sequence, with orbitofrontal cortex. Similar stepwise links exist between areas on the visual and auditory association pathways in the occipitotemporal lobe and areas of the frontal association cortex. The connections between sensory and association areas are reciprocal.

All neocortical areas are connected with subcortical regions although their density varies between areas. First among these are connections with the thalamus. All areas of the neocortex receive afferents from more than one thalamic nucleus, and all such connections are reciprocal. The vast majority of, if not all, cortical areas project to the striatum, tectum, pons and brain stem reticular formation. Additionally, all cortical areas are reciprocally connected with the claustrum; the frontal cortex connects with the anterior
part and the occipital lobe with the posterior part.

All cortical areas receive topographically organized cholinergic projections from the basal forebrain, noradrenergic fibres from the locus coeruleus, serotonergic fibres from the midbrain raphe nuclei, dopaminergic fibres from the ventral midbrain and histaminergic fibres from the posterior hypothalamus.

Different cortical areas have widely different afferent and efferent connections. Some have connections that are unique, e.g. the corticospinal tract arises from pyramidal cells in a restricted area around the central sulcus.

Widely separated, but functionally interconnected, areas of cortex share common patterns of connections with subcortical nuclei, and within the neocortex. For example, contiguous zones of the striatum, thalamus, claustrum, cholinergic basal forebrain, superior colliculus and pontine nuclei connect with anatomically widely separated areas in the prefrontal and parietal cortex, which are themselves interconnected. In contrast, other functionally distinct cortical regions, e.g. areas in the temporal and parietal cortex, do not share such contiguity in their subcortical connections.

**Cortical lamination and cortical connections**

The cortical laminae represent, to some extent, horizontal aggregations of neurones with common connections. This is most clearly seen in the lamination of cortical efferent (pyramidal) cells. The internal pyramidal lamina, layer V, gives rise to cortical projection fibres, most notably corticostriate, corticobulbar (including corticopontine) and corticospinal axons. In addition, a significant proportion of feedback corticocortical axons arise from cells in this layer, as do some corticothalamic fibres. Layer VI, the multiiform lamina, is the major source of corticothalamic fibres. Supragranular pyramidal cells, predominantly layer III, but also lamina II, give rise primarily to both association and commissural corticocortical pathways. Generally, short corticocortical fibres arise more superficially, and long corticocortical (both association and commissural) axons come from cells in the deeper parts of layer III. Major afferents to a cortical area tend to terminate in layers I, IV and VI. Quantitatively lesser projections end either in the intervening laminae II/III and V, or sparsely throughout the depth of the cortex. Numerically, the largest input to a cortical area tends to terminate mainly in layer IV. This pattern of termination is seen in the major thalamic input to visual and somatic sensory cortex. In general, non-thalamic subcortical afferents to the neocortex, which are shared by widespread areas, tend to terminate throughout all cortical layers, but the laminar pattern of their endings still varies considerably from area to area.
Columns and modules

Experimental physiological and connectional studies have demonstrated an internal organization of the cortex, which is at right angles to the pial surface, with vertical columns or modules running through the depth of the cortex. The term ‘column’ refers to the observation that all cells encountered by a microelectrode penetrating and passing perpendicularly through the cortex respond to a single peripheral stimulus, a phenomenon first identified in the somatosensory cortex. In the visual cortex, narrow (50 µm) vertical strips of neurones respond to a bar stimulus of the same orientation (orientation columns) and wider strips (500 µm) respond preferentially to stimuli detected by one eye (ocular dominance columns). Adjacent orientation columns aggregate within an ocular dominance column to form a hypercolumn, responding to all orientations of stimulus for both eyes for one point in the visual field. Similar functional columnar organization has been described in widespread areas of neocortex, including motor cortex and association areas.
FRONTAL LOBE

The frontal lobe is the rostral region of the hemisphere, anterior to the central sulcus and above the lateral fissure. The precentral gyrus runs parallel to the central sulcus on the superolateral surface and extends onto the medial surface, and is limited anteriorly by the precentral sulcus. The area of the frontal lobe anterior to the precentral sulcus is divided into the superior, middle and inferior frontal gyri (Fig. 23.1). The frontal pole lies in front of these gyri. The ventral surface of the frontal lobe, the orbitofrontal cortex, overlies the bony orbit. The medial surface extends from the frontal pole to the paracentral lobule and consists of the medial frontal cortex and the anterior cingulate cortex.

Primary motor cortex

The primary motor cortex (MI) corresponds to the precentral gyrus (area 4), and is the area of cortex with the lowest threshold for eliciting contralateral muscle contraction by electrical stimulation. It contains a detailed topographically organized map (motor homunculus) of the opposite body half, with the head represented most laterally, and the leg and foot represented on the medial surface of the hemisphere in the paracentral lobule (Fig. 23.9). A striking feature is the disproportionate representation of body parts in relation to their physical size: large areas represent the muscles of the face and hand, which are capable of finely controlled or fractionated movements.
The cortex of area 4 is agranular, and layers II and IV are difficult to identify. The most characteristic feature is the presence in lamina V of some extremely large pyramidal cell bodies, Betz cells, which may approach 80 µm in diameter. These neurones project their axons into the corticospinal and corticobulbar tracts.

The major thalamic connections of area 4 are with the ventral posterolateral nucleus (VPL), which in turn receives afferents from the deep cerebellar nuclei. The VPL nucleus also contains a topographic representation of the contralateral body, which is preserved in its point-to-point projection to area 4, where it terminates largely in lamina IV. Other thalamic connections of area 4 are with the centromedian and parafascicular nuclei. These appear to provide the only route through which output from the basal ganglia, routed via the thalamus, reaches the primary motor cortex,
since the projection of the internal segment of the globus pallidus to the ventrolateral nucleus of the thalamus is confined to the anterior division, and there is no overlap with cerebellothalamic territory. The anterior part of the ventrolateral nucleus projects to the premotor and supplementary motor areas of cortex with no projection to area 4.

The ipsilateral somatosensory cortex (SI) projects in a topographically organized way to area 4, and the connection is reciprocal. The projection to the motor cortex arises in areas 1 and 2, with little or no contribution from area 3b. Fibres from SI terminate in layers II and III of area 4, where they contact mainly pyramidal neurones. Evidence suggests that neurones activated monosynaptically by fibres from SI, as well as those activated polysynaptically, make contact with layer V pyramidal cells, including Betz cells, which give rise to corticospinal fibres. Movement-related neurones in the motor cortex which can be activated from SI tend to have a late onset of activity, mainly during the execution of movement. It has been suggested that this pathway plays a role primarily in making motor adjustments during a movement. Additional ipsilateral corticocortical fibres to area 4 from behind the central sulcus come from the second somatic sensory area (SII).

Neurones in area 4 are responsive to peripheral stimulation, and have receptive fields similar to those in the primary sensory cortex. Cells located posteriorly in the motor cortex have cutaneous receptive fields, whereas more anteriorly situated neurones respond to stimulation of deep tissues.

The motor cortex receives major frontal lobe association fibres from the premotor cortex and the supplementary motor area and also fibres from the insula. It is probable that these pathways modulate motor cortical activity in relation to the preparation, guidance and temporal organization of movements. Area 4 sends fibres to, and receives fibres from, its contralateral counterpart, and also projects to the contralateral supplementary motor cortex.

Apart from its contribution to the corticospinal tract, the motor cortex has diverse subcortical projections. The connections to the striatum and pontine nuclei are heavy. It also projects to the subthalamic nucleus. The motor cortex sends projections to all nuclei in the brain stem, which are themselves the origin of descending pathways to the spinal cord, namely the reticular formation, the red nucleus, the superior colliculus, the vestibular nuclei and the inferior olivary nucleus.

**Corticospinal tract**

The corticospinal or pyramidal tract provides direct control by the cerebral cortex over motor centres of the spinal cord. An homologous pathway to the brain stem, the corticobulbar projection, fulfils a similar function in relation to motor nuclei of the brain stem. The corticospinal tract does not originate solely from the motor cortex, but is conveniently considered in conjunction with it.

The percentage of corticospinal fibres that arise from the primary motor cortex may actually be quite small, probably in the region of 20 to 30%. They arise from pyramidal cells in layer V and give rise to the largest diameter corticospinal axons. There is also a widespread origin from other parts of the frontal lobe, including the premotor cortex and the supplementary motor area. Many axons from the frontal cortex, notably the motor cortex, terminate in the ventral horn of the spinal cord. In cord segments
mediating dexterous hand and finger movements they terminate in the lateral part of
the ventral horn, in close relationship to motor neuronal groups. A small percentage
establish direct monosynaptic connections with α motor neurones.

Between 40 and 60% of pyramidal tract axons arise from parietal areas, including
area 3a, area 5 of the superior parietal lobe, and SII in the parietal operculum. The
majority of parietal fibres to the spinal cord terminate in the deeper layers of the dorsal
horn.

Motor cortical neurones are active in relation to the force of contraction of agonist
muscles; their relation to amplitude of movement is less clear. Their activity precedes
the onset of electromyographic activity by 50 to 100 milliseconds, suggesting a role for
cortical activation in generating rather than monitoring movement.

**Premotor cortex**

Immediately in front of the primary motor cortex lies Brodmann's area 6. It extends
onto the medial surface, where it becomes contiguous with area 24 in the cingulate
gyrus, anterior and inferior to the paracentral lobule. A number of functional motor
areas are contained within this cortical region. Lateral area 6, the area over most of
the lateral surface of the hemisphere, corresponds to the premotor cortex.

The premotor cortex is divided into a dorsal and a ventral area (PMd and PMv
respectively) on functional grounds, and on the basis of ipsilateral corticocortical
association connections.

The major thalamic connections of the premotor cortex are with the anterior division of
the ventrolateral nucleus and with the centromedian, parafascicular and centrolateral
components of the intralaminar nuclei. Subcortical projections to the striatum and
pontine nuclei are prominent, and this area also projects to the superior colliculus and
the reticular formation. Both dorsal and ventral areas contribute to the corticospinal
tract. Commissural connections are with the contralateral premotor, motor and
superior parietal (area 5) cortex. Ipsilateral corticocortical connections with area 5 in
the superior parietal cortex, and inferior parietal area 7b are common to both dorsal
and ventral subdivisions of the premotor cortex, and both send a major projection to
the primary motor cortex. The dorsal premotor area also receives fibres from the
posterior superior temporal cortex and projects to the supplementary motor cortex.
The frontal eye field (area 8) projects to the dorsal subdivision. Perhaps the greatest
functionally significant difference in connectivity between the two premotor area
subdivisions is that the dorsal premotor area receives fibres from the dorsolateral
prefrontal cortex, whereas the ventral subdivision receives fibres from the ventrolateral
prefrontal cortex. All of these association connections are likely to be, or are known to
be, reciprocal.

Neuronal activity in the premotor cortex in relation to both preparation for movement
and movement itself has been extensively studied experimentally. Direction selectivity
for movement is a common feature of many premotor neurones. In behavioural tasks,
neurones in the dorsal premotor cortex show anticipatory activity and task-related
discharge as well as direction selectivity, but little or no stimulus-related changes. The
dorsal premotor cortex is probably important in establishing a motor set or intention,
contributing to motor preparation in relation to internally guided movement. In contrast,
ventral premotor cortex is more related to the execution of externally (especially visually) guided movements in relation to a specific external stimulus.

**Frontal eye field**

The frontal eye field corresponds to parts of Brodmann's areas 6, 8 and 9 (Fig. 23.10). It receives its major thalamic projection from the parvocellular mediodorsal nucleus, with additional afferents from the medial pulvinar, the ventral anterior nucleus and the suprageniculate–limitans complex, and connects with the paracentral nucleus of the intralaminar group. The thalamocortical pathways to the frontal eye field form part of a pathway from the superior colliculus, the substantia nigra and the dentate nucleus of the cerebellum. The frontal eye field has extensive ipsilateral corticocortical connections, receiving fibres from several visual areas in the occipital, parietal and temporal lobes, including the medial temporal area (V5) and area 7a. There is also a projection from the superior temporal gyrus, which is auditory rather than visual in function. From within the frontal lobe, the frontal eye field receives fibres from the ventrolateral and dorsolateral prefrontal cortices. It projects to the dorsal and ventral premotor cortices and to the medial motor area, probably to the supplementary eye field adjacent to the supplementary motor area proper. It projects prominently to the superior colliculus, to the pontine gaze centre within the pontine reticular formation, and to other oculomotor related nuclei in the brain stem. As its name implies, it is important in the control of eye movements.

![Fig. 23.10](image) Lateral surface of the left cerebral hemisphere showing the frontal eye field (parts of areas 6, 8, 9), the motor speech (Broca's) area (areas 44, 45) and Wernicke's area. The perimeter of these areas is delineated by an interrupted line to indicate uncertainty as to their precise extent. Wernicke's area is variously depicted by different authorities as encompassing a large parietotemporal area which includes areas 39 and 40. Areas 22 and 37 are considered by some to be respectively auditory and visuo-auditory areas associated with speech and language.
**Supplementary motor cortex**

The supplementary motor area (SMA; MII) lies medial to area 6, and extends from the most superolateral part to the medial surface of the hemisphere. Area 24 in the cingulate gyrus adjacent to area 6 contains several motor areas, which are termed cingulate motor areas. An additional functional subdivision, the preSMA, lies anterior to the supplementary motor area on the medial surface of the cortex. In the present discussion, these additional medial motor areas are included with the supplementary motor cortex.

The supplementary motor area receives its major thalamic input from the anterior part of the ventral lateral nucleus, which in turn is the major recipient of fibres from the internal segment of the globus pallidus. Additional thalamic afferents are from the ventral anterior nucleus, the intralaminar nuclei, notably the centrolateral and centromedial nuclei, and also from the mediodorsal nucleus. The connections with the thalamus are reciprocal. The supplementary motor cortex receives connections from widespread regions of the ipsilateral frontal lobe, including from the primary motor cortex, the dorsal premotor area, the dorsolateral and ventrolateral prefrontal, medial prefrontal and orbitofrontal cortex and the frontal eye field. These connections are reciprocal, but the major ipsilateral efferent pathway is to the motor cortex. Parietal lobe connections of the supplementary motor cortex are with the superior parietal area 5 and possibly inferior parietal area 7b. Contralateral connections are with the supplementary motor area, and motor and premotor cortices of the contralateral hemisphere. Subcortical connections, other than with the thalamus, pass to the striatum, subthalamic nucleus and pontine nuclei, the brain stem reticular formation and the inferior olivary nucleus. The supplementary motor area makes a substantial contribution to the corticospinal tract, contributing as much as 40% of the fibres from the frontal lobe.

The supplementary motor area contains a representation of the body in which the leg is posterior and the face anterior, with the upper limb between them. Its role in the control of movement is primarily in complex tasks which require temporal organization of sequential movements and in the retrieval of motor memory.

Stimulation of the supplementary motor area in conscious patients has been reported to elicit the sensation of an urge to move, or of anticipation that a movement is about to occur. A region anterior to the supplementary motor area for face representation (areas 44, 45) is important in vocalization and speech production (Fig. 23.10).

**Prefrontal cortex**

The prefrontal cortex on the lateral surface of the hemisphere comprises predominantly Brodmann's areas 9, 46 and 45 (Fig. 23.8). In non-human primates, two subdivisions of the lateral prefrontal cortex are recognized, a dorsal area equivalent to area 9, and perhaps including the superior part of area 46, and a ventral area, consisting of the inferior part of area 46 and area 45. Areas 44 and 45 are particularly notable in man since, in the dominant hemisphere, they constitute the motor speech area (Broca's area). Both the dorsolateral and ventrolateral prefrontal areas receive their major thalamic afferents from the mediodorsal nucleus, and there
are additional contributions from the medial pulvinar, the ventral anterior nucleus and from the paracentral nucleus of the anterior intralaminar group. The dorsolateral area receives long association fibres from the posterior and middle superior temporal gyrus (including auditory association areas), from parietal area 7a, and from much of the middle temporal cortex. From within the frontal lobe it also receives projections from the frontal pole (area 10), and from the medial prefrontal cortex (area 32) on the medial surface of the hemisphere. It projects to the supplementary motor area, the dorsal premotor cortex and the frontal eye field. All these thalamic and corticocortical connections are reciprocal. Commissural connections are with the homologous area, and with the contralateral inferior parietal cortex. The ventrolateral prefrontal area receives long association fibres from both area 7a and area 7b of the parietal lobe, from auditory association areas of the temporal operculum, from the insula and from the anterior part of the lower bank of the superior temporal sulcus. From within the frontal lobe it receives fibres from the anterior orbitofrontal cortex and projects to the frontal eye field and the ventral premotor cortex. It connects with the contralateral homologous area via the corpus callosum. These connections are probably all reciprocal.

The cortex of the frontal pole (area 10) receives thalamic input from the mediodorsal nucleus, the medial pulvinar and the paracentral nucleus. It is reciprocally connected with the cortex of the temporal pole, the anterior orbitofrontal cortex, and the dorsolateral prefrontal cortex. The orbitofrontal cortex connects with the mediodorsal, anteromedial, ventral anterior, medial pulvinar, paracentral and midline nuclei of the thalamus. Cortical association pathways come from the inferotemporal cortex, the anterior superior temporal gyrus and the temporal pole. Within the frontal lobe it has connections with the medial prefrontal cortex, the ventrolateral prefrontal cortex and medial motor areas. Commissural and other connections follow the general pattern for all neocortical areas.

The medial prefrontal cortex is connected with the mediodorsal, ventral anterior, anterior medial pulvinar, paracentral, midline and suprageniculate–limitans nuclei of the thalamus. It receives fibres from the anterior cortex of the superior temporal gyrus. Within the frontal lobe, it has connections with the orbitofrontal cortex, and the medial motor areas of the dorsolateral prefrontal cortex.
PARIETAL LOBE

The parietal lobe lies posterior to the central sulcus. On the medial aspect of the hemisphere its boundary with the occipital lobe is clearly demarcated by the deep parieto-occipital sulcus. On the lateral aspect of the hemisphere its boundaries with the occipital and temporal lobes are less distinct and somewhat arbitrary. The inferior boundary is the posterior ramus of the lateral fissure and its imaginary posterior prolongation.

The lateral aspect of the parietal lobe is divided into three areas by postcentral and intraparietal sulci (Fig. 23.1). The postcentral sulcus, often divided into upper and lower parts, is posterior and parallel to the central sulcus. Inferiorly, it ends above the posterior ramus of the lateral fissure. The postcentral gyrus or primary somatosensory cortex lies between the central and postcentral sulci. Posterior to the postcentral sulcus there is a large area, subdivided by the intraparietal sulcus. It usually starts in the postcentral sulcus near its midpoint and extends posteroinferiorly across the parietal lobe, dividing the latter into superior and inferior parietal lobules.

The superior parietal lobule, between the superomedial margin of the hemisphere and the intraparietal sulcus, is continuous anteriorly with the postcentral gyrus round the upper end of the postcentral sulcus.

The inferior parietal lobule, below the intraparietal sulcus and behind the lower part of the postcentral sulcus, is divided into three. The anterior part is the supramarginal gyrus, which arches over the upturned end of the lateral fissure. It is continuous anteriorly with the lower part of the postcentral gyrus and posteroinferiorly with the superior temporal gyrus. The middle part of the inferior parietal lobule, called the angular gyrus, arches over the end of the superior temporal sulcus and is continuous posteroinferiorly with the middle temporal gyrus. The posterior part of the inferior parietal lobule arches over the upturned end of the inferior temporal sulcus on to the occipital lobe.

Somatosensory cortex

The postcentral gyrus corresponds to the primary somatosensory cortex (SI; Brodmann's areas 3a, 3b, 1 and 2). Area 3a lies most anteriorly, apposing area 4, the primary motor cortex of the frontal lobe; area 3b is buried in the posterior wall of the central sulcus; area 1 lies along the posterior lip of the central sulcus; and area 2 occupies the crown of the postcentral gyrus.

The primary somatosensory cortex contains within it a topographical map of the contralateral half of the body. The face, tongue and lips are represented inferiorly, the trunk and upper limb are represented on the superolateral aspect, and the lower limb on the medial aspect of the hemisphere, giving rise to the familiar ‘homunculus' map (Fig. 23.9).
The somatosensory properties of SI depend on its thalamic input from the ventral posterior nucleus of the thalamus, which in turn receives the medial lemniscal, spinothalamic and trigeminothalamic pathways. The nucleus is divided into a ventral posterolateral part, which receives information from the trunk and limbs, and a ventral posteromedial part, in which the head is represented. Within the ventral posterior nucleus, neurones in the central core respond to cutaneous stimuli and those in the most dorsal anterior and posterior parts, which arch as a ‘shell’ over this central core, respond to deep stimuli. This is reflected in the differential projections to SI: the cutaneous central core projects to 3b, the deep tissue-responsive neurones send fibres to areas 3a and 2, and an intervening zone projects to area 1. Within the ventral posterior nucleus, anteroposterior rods of cells respond with similar modality and somatotopic properties. They appear to project to restricted focal patches in SI of approximately 0.5 mm width, which form narrow strips mediolaterally along SI. The laminar termination of thalamocortical axons from the ventral posterior nucleus is different in the separate cytoarchitectonic subdivisions of SI. In 3a and 3b, these axons terminate mainly in layer IV and the adjacent deep part of layer III, whereas in areas 1 and 2 they end in the deeper half of layer III, avoiding lamina IV. Additional thalamocortical fibres to SI arise from the intralaminar system, notably the centrolateral nucleus.

There is a complex internal connectivity within SI. An apparently stepwise hierarchical progression of information processing occurs from area 3b through area 1 to area 2. Outside the postcentral gyrus, SI has ipsilateral corticocortical association connections with a second somatosensory area (SII); area 5 in the superior parietal lobe; area 4, the motor cortex, in the precentral gyrus; and the supplementary motor cortex in the medial part of area 6 of the frontal lobe.

SI has reciprocal commissural connections with its contralateral homologue, with the exception that the cortices containing the representation of the distal extremities are relatively devoid of such connections. Callosal fibres in SI arise mainly from the deep part of layer III and terminate in layers I to IV. Pyramidal cells contributing callosal projections receive monosynaptic thalamic and commissural connections.

SI has reciprocal subcortical connections with the thalamus and claustrum, and receives afferents from the basal nucleus of Meynert, the locus coeruleus and the midbrain raphe. It has other prominent subcortical projections. Corticostriatal fibres, arising in layer V, pass mainly to the putamen of the same side. Corticopontine and corticotectal fibres from SI arise in layer V. SI projects to the main pontine nuclei, and to the pontine tegmental reticular nucleus. In addition, axons arising in SI pass to the dorsal column nuclei and the spinal cord. Corticospinal pyramidal cells are found in layer V of SI. The topographical representation in the cortex is preserved in
terms of the spinal segments to which different parts of the postcentral gyrus project. Thus, the arm representation projects to the cervical enlargement, the leg representation to the lumbosacral enlargement, and so on. Within the grey matter of the spinal cord, fibres from SI terminate in the dorsal horn, in Rexed's laminae 3 to 5: fibres from 3b and 1 end more dorsally, and those from area 2 more ventrally.

The second somatosensory area (SII) lies along the upper bank of the lateral fissure, posterior to the central sulcus. SII contains a somatotopic representation of the body, with the head and face most anteriorly, adjacent to SI, and the sacral regions most posteriorly. SII is reciprocally connected with the ventral posterior nucleus of the thalamus in a topographically organized fashion. Some thalamic neurones probably project to both SI and SII via axon collaterals. Other thalamic connections of SII are with the posterior group of nuclei and with the intralaminar central lateral nucleus. SII also projects to laminae IV to VII of the dorsal horn of the cervical and thoracic spinal cord, the dorsal column nuclei, the principal trigeminal nucleus, and the periaqueductal grey matter of the midbrain.

Within the cortex, SII is reciprocally connected with SI in a topographically organized manner, and projects to the primary motor cortex. SII also projects in a topographically organized way to the lateral part of area 7 (area 7b) in the superior parietal lobe, and makes connections with the posterior cingulate gyrus. Both right and left SII areas are interconnected across the corpus callosum, although distal limb representations are probably excluded. There are additional callosal projections to SI and area 7b.

Experimental studies show that neurones in SII respond particularly to transient cutaneous stimuli, e.g. brush strokes or tapping, which are characteristic of the responses of Pacinian corpuscles in the periphery. They show little response to maintained stimuli.

**Superior and inferior parietal lobules**

Posterior to the postcentral gyrus, the superior part of the parietal lobe is composed of areas 5, 7a and 7b (Fig. 23.8). Area 5 receives a dense feedforward projection from all cytoarchitectonic areas of SI in a topographically organized manner. The thalamic afferents to this area come from the lateral posterior nucleus and from the central lateral nucleus of the intralaminar group. Ipsilateral corticocortical fibres from area 5 go to area 7, the premotor and supplementary motor cortices, the posterior cingulate gyrus, and the insular granular cortex. Commissural connections between area 5 on both sides tend to avoid the areas of representation of the distal limbs. The response properties of cells in area 5 are more complex than in SI, with larger receptive fields and evidence of submodality convergence. Area 5 contributes to the corticospinal tract.
In non-human primates, the inferior parietal lobe is area 7. In man, this area is more superior, and areas 39 and 40 intervene inferiorly. The counterparts for the latter areas in monkeys are unclear and little experimental evidence is available on their connections and functions. Their role in human cerebral processing is discussed below. In the monkey, area 7b receives somatosensory inputs from area 5 and SII. Connections pass to the posterior cingulate gyrus (area 23), insula and temporal cortex. Area 7b is reciprocally connected with area 46 in the prefrontal cortex and the lateral part of the premotor cortex. Commissural connections of area 7b are with the contralateral homologous area, and with SII, the insular granular cortex and area 5. Thalamic connections are with the medial pulvinar nucleus and the intralaminar paracentral nucleus.

In monkeys, area 7a is not related to the cortical pathways for somatosensory processing, but instead forms part of a dorsal cortical pathway for spatial vision. The major ipsilateral corticocortical connections to area 7a are derived from visual areas in the occipital and temporal lobes. In the ipsilateral hemisphere, area 7a has connections with the posterior cingulate cortex (area 24) and with areas 8 and 46 of the frontal lobe. Commissural connections are with its contralateral homologue. Area 7a is connected with the medial pulvinar and intralaminar paracentral nuclei of the thalamus. In experimental studies, neurones within area 7a are visually responsive: they relate largely to peripheral vision, respond to stimulus movement, and are modulated by eye movement.
TEMPORAL LOBE

The temporal lobe is inferior to the lateral fissure. It is limited behind by an arbitrary line from the preoccipital incisure to the parieto-occipital sulcus which meets the superomedial margin of the hemisphere approximately 5 cm from the occipital pole. Its lateral surface is divided into three parallel gyri by the superior and inferior temporal sulci.

The superior temporal sulcus begins near the temporal pole and slopes slightly up and backwards parallel to the posterior ramus of the lateral sulcus. Its end curves up into the parietal lobe. The inferior temporal sulcus is subjacent and parallel to the superior and is often broken into two or three short sulci. Its posterior end also ascends into the parietal lobe, posterior and parallel to the upturned end of the superior sulcus.

The three parallel gyri on the lateral surface of the temporal lobe are the superior (area 22); middle (area 21); and inferior (area 20) temporal gyri. The temporal pole (area 38) lies in front of the termination of these gyri. Along its superior margin the superior temporal gyrus is continuous with gyri in the floor of the posterior ramus of the lateral sulcus. These vary in number, and extend obliquely anterolaterally from the circular sulcus around the insula as the transverse temporal gyri of Heschl (Fig. 23.11). The anterior transverse temporal gyrus and adjoining part of the superior temporal gyrus are auditory in function, and are considered to be Brodmann's area 42. The anterior gyrus is approximately area 41.
Fig. 23.11 Horizontal section showing the left temporal lobe, viewed from above.

The cortex of the medial temporal lobe includes major subdivisions of the limbic system, such as the hippocampus and entorhinal cortex. Areas of neocortex adjacent to these limbic regions are grouped together as medial temporal association cortex. The temporal and frontal lobes are expanded enormously in man, which poses a problem when relating physiological and anatomical studies of non-human primates to human brain topography. In general, the commonly studied old world monkeys lack a middle temporal gyrus.

**Auditory cortex**

The temporal operculum houses the primary auditory cortex, AI. This is coextensive with the granular area 41 in the transverse temporal gyri. Surrounding areas constitute auditory association cortex. The primary auditory cortex is reciprocally connected with all subdivisions of the medial geniculate nucleus, and may receive additional thalamocortical projections from the medial pulvinar. The geniculocortical fibres terminate densely in layer IV. AI contains a tonotopic representation of the cochlea in which high frequencies are represented posteriorly, and low frequencies anteriorly. Single-cell responses are to single tones of a narrow frequency band. Cells in single vertical electrode penetrations share an optimum frequency response.

The auditory cortex interconnects with prefrontal cortex, though the projections from
AI are small. In general, posterior parts of the operculum project to areas 8 and 9. Central parts project to areas 8, 9 and 46. More anterior regions project to areas 9 and 46, to area 12 on the orbital surface of the hemisphere, and to the anterior cingulate gyrus on the medial surface. Contralateral corticocortical connections are with the same and adjacent regions in the other hemisphere. Onward connections of the auditory association pathway converge with those of the other sensory association pathways in cortical regions within the superior temporal sulcus.

Evidence suggests that area 21, the middle temporal cortex, is polysensory in man, and that it connects with auditory, somatosensory and visual cortical association pathways. The auditory association areas of the superior temporal gyrus project in a complex ordered fashion to the middle temporal gyrus, as does the parietal cortex. The middle temporal gyrus connects with the frontal lobe: the most posterior parts project to posterior prefrontal cortex, areas 8 and 9, while intermediate regions connect more anteriorly with areas 19 and 46. Further forwards, the middle temporal region has connections with anterior prefrontal areas 10 and 46, and with anterior orbitofrontal areas 11 and 14. The most anterior middle temporal cortex is connected with the posterior orbitofrontal cortex, area 12, and with the medial surface of the frontal pole. Further forwards, this middle temporal region projects to the temporal pole and the entorhinal cortex. Thalamic connections are with the pulvinar nuclei and the intralaminar group. Other subcortical connections follow the general pattern for all cortical areas. Some projections (e.g. to the pons), particularly from anteriorly in the temporal lobe, are minimal. Physiological responses of cells in this middle temporal region show convergence of different sensory modalities, and many neurones respond to faces.

The inferior temporal cortex, area 20, is a higher visual association area. The posterior inferior temporal cortex receives major ipsilateral corticocortical fibres from occipitotemporal visual areas, notably V4. It contains a coarse retinotopic representation of the contralateral visual field, and sends a major feedforward pathway to the anterior part of the inferior temporal cortex. The anterior inferior temporal cortex projects onto the temporal pole and to paralimbic areas on the medial surface of the temporal lobe. Additional ipsilateral association connections of the inferior temporal cortex are with the anterior middle temporal cortex, in the walls of the superior temporal gyrus, and with visual areas of the parietotemporal cortex. Frontal lobe connections are with area 46 in the dorsolateral prefrontal cortex (posterior inferior temporal), and with the orbitofrontal cortex (anterior inferior temporal). The posterior area also connects with the frontal eye field. Reciprocal thalamic connections are with the pulvinar nuclei; the posterior part is related mainly to the inferior and lateral nuclei, and the anterior part to the medial and adjacent lateral pulvinar. Intralaminar connections are with the paracentral and central medial nuclei. Other subcortical connections conform to the general pattern of all cortical regions. Callosal connections are between corresponding areas and the adjacent visual association areas of each hemisphere.

The cortex of the temporal pole receives feedforward projections from widespread areas of temporal association cortex which are immediately posterior to it. The dorsal part receives predominantly auditory input from the anterior part of the superior temporal gyrus. The inferior part receives visual input from the anterior area of the inferior temporal cortex. Other ipsilateral connections are with the anterior insular, the posterior and medial orbitofrontal, and the medial prefrontal cortices. The temporal
pole projects onwards into limbic and paralimbic areas. Thalamic connections are mainly with the medial pulvinar nucleus, and with intralaminar and midline nuclei. Other subcortical connections are as for the cortex in general, although some projections, such as that to the pontine nuclei, are very small. Physiological responses of cells in this and more medial temporal cortex correspond particularly to behavioural performance and to the recognition of high-level aspects of social stimuli.

Nuclei of the amygdala project to, and receive fibres from, neocortical areas, predominantly of the temporal lobe, and possibly inferior parietal cortex. The density of these pathways increases towards the temporal pole.
INSULA

The insula (Fig. 23.12) lies deep in the floor of the lateral fissure, almost surrounded by a circular sulcus, and overlapped by adjacent cortical areas, the opercula. The frontal operculum is between the anterior and ascending rami of the lateral fissure, forming a triangular division of the inferior frontal gyrus. The frontoparietal operculum, between ascending and posterior rami of the lateral fissure, consists of the posterior part of the inferior frontal gyrus, the lower ends of the precentral and postcentral gyri, and the lower end of the anterior part of the inferior parietal lobule. The temporal operculum, below the posterior ramus of the lateral fissure, is formed by superior temporal and transverse temporal gyri. Anteriorly, the inferior region of the insula adjoins the orbital part of the inferior frontal gyrus.

When the opercula are removed, the insula appears as a pyramidal area, its apex beneath and near the anterior perforated substance, where the circular sulcus is deficient. The medial part of the apex is termed the limen insulae (gyrus ambiens). A central insular sulcus, which slants posterosuperiorly from the apex, divides the insular surface into a large anterior and a small posterior part. The anterior part is divided by shallow sulci into three or four short gyri, whereas the posterior part is one long gyrus, often divided at its upper end. The cortex of the insula is continuous with that of its opercula in the circular sulcus. The insula is approximately coextensive with the subjacent claustrum and putamen.
Cytoarchitectonically, three zones are recognized within the insula. Anteriorly, and extending caudally into the central insula, the cortex is agranular. It is surrounded by a belt of dysgranular cortex, in which laminae II and III can be recognized, and this in turn is surrounded by an outer zone of homotypical granular cortex which extends to the caudal limit of the insula.

Thalamic afferents to the insula come from subdivisions of the ventral posterior nucleus and of the medial geniculate body, from the oral and medial parts of the pulvinar, the suprageniculate/nucleus limitans complex, the mediodorsal nucleus and the nuclei of the intralaminar and midline groups. It appears that the anterior (agranular) cortex is connected predominantly with the mediodorsal and ventroposterior nuclei, while the posterior (granular) cortex is connected predominantly with the pulvinar and the ventral posterior nuclei. The other nuclear groups appear to connect with all areas.

Ipsilateral cortical connections of the insula are diverse. Somatosensory connections are with SI, SII and surrounding areas, area 5 of the superior parietal lobe and area 7b of the inferior parietal lobe. The insular cortex also has connections with the orbitofrontal cortex. Several auditory regions in the temporal lobe interconnect with the posterior granular insula and the dysgranular cortex more anteriorly. Connections with visual areas are virtually absent. The anterior agranular cortex of the insula appears to have connections primarily with olfactory, limbic and paralimbic structures, including, most prominently, the amygdala. Little is known about the functions of the human insula other than that the anterior insular cortex appears to have a role in olfaction and taste and the posterior part in somatosensory functions. The latter has also been implicated in language functions, which resonates with the possibility that higher order auditory association pathways may pass via areas in the insula.

**Clastrum**

The claustrum (see Fig. 23.27) is a thin sheet of grey matter lying deep to the insula. It is approximately coextensive with the insula, from which it is separated by the extreme capsule. Medially, the claustrum is separated from the putamen by the external capsule. It is thickest anteriorly and inferiorly, where it becomes continuous with the anterior perforated substance, amygdala and prepiriform cortex. In animals, it has reciprocal, topographically organized, connections with many regions of the neocortex. Little is known about the connections and functional significance of the claustrum in the human brain.
Fig. 23.27 Superior aspect of a horizontal section through the left cerebral hemisphere.
OCCIPITAL LOBE

The occipital lobe lies behind an arbitrary line joining the preoccipital incisure and the parieto-occipital sulcus (Fig. 23.1, Fig. 23.2) and is comprised almost entirely of Brodmann's areas 17, 18 and 19. Area 17, the striate cortex, is the primary visual cortex (VI). A host of other distinct visual areas reside in the occipital and temporal cortex. Functional subdivisions V2, V3 (dorsal and ventral) and V3A lie within Brodmann's area 18. Other functional areas at the junction of the occipital cortex with the parietal or temporal lobes lie wholly or partly in area 19.

The primary visual cortex is mostly located on the medial aspect of the occipital lobe, and is coextensive with the subcortical nerve fibre stria of Gennari in layer IV; hence its alternative name, the striate cortex. It occupies the upper and lower lips and depths of the posterior part of the calcarine sulcus and extends into the cuneus and lingual gyrus.

The primary visual cortex receives afferent fibres from the lateral geniculate nucleus via the optic radiation (see Fig. 23.27). The latter curves posteriorly and spreads through the white matter of the occipital lobe. Its fibres terminate in strict point-to-point fashion in the striate area. The cortex of each hemisphere receives impulses from two hemi-retinae, which represent the contralateral half of the binocular visual field. Superior and inferior retinal quadrants are connected with corresponding areas of the striate cortex. Thus, the superior retinal quadrants (representing the inferior half of the visual field) are connected with the visual cortex above the calcarine sulcus, and the inferior retinal quadrants (representing the upper half of the visual field) are connected with the visual cortex below the calcarine sulcus. The peripheral parts of the retinae activate the most anterior parts in the visual cortex. The macula impinges upon a disproportionately large posterior part around the occipital pole.

The striate cortex is granular. Layer IV, bearing the stria of Gennari, is commonly divided into three sublayers. Passing from superficial to deep, these are IVA, IVB (which contains the stria), and IVC. The densely cellular IVC is further subdivided into a superficial IVCα and a deep IVCβ. Layer IVB contains only sparse, mainly non-pyramidal, neurones. The input to area 17 from the lateral geniculate nucleus terminates predominantly in layers IVA and IVC. Other thalamic afferents, from the inferior pulvinar nucleus and the intralaminar group, pass to layers I and VI. Geniculocortical fibres terminate in alternating bands. Axons from geniculate laminae which receive information from the ipsilateral eye (laminae 2, 3 and 5), are segregated from those of laminae which receive input from the contralateral eye (laminae 1, 4 and 6). Neurones within layer IVC are monocular, i.e. they respond to stimulation of either the ipsilateral or contralateral eye, but not both. This horizontal segregation forms the anatomical basis of the ocular dominance
column in that neurones encountered in a vertical strip from pia to white matter, although binocular outside layer IV, exhibit a preference for stimulation of one or other eye. The other major functional basis for visual cortical columnar organization is the orientation column. This describes the observation that an electrode passing through the depth of the cortex at right angles to the plane from pia to white matter, encounters neurones that all respond preferentially to either a stationary or a moving straight line of a given orientation within the visual field. Cells with simple, complex and hypercomplex receptive fields occur in area 17. Simple cells respond optimally to lines in a narrowly defined position. Complex cells respond to a line anywhere within a receptive field, but with a specific orientation. Hypercomplex cells are similar to complex cells except that the length of the line or bar stimulus is also critical for an optimal response. There is a relationship between the complexity of response and the position of cells in relation to the cortical laminae. Simple cells are mainly in layer IV and complex and hypercomplex cells predominate in either layers II and III or layers V and VI.

Ipsilateral corticocortical fibres pass from area 17 to a variety of functional areas in areas 18 and 19 and in the parietal and temporal cortices. Fibres from area 17 pass to area 18 (which contains visual areas V2, V3 and V3a); area 19 (which contains V4); the posterior intraparietal and the parieto-occipital areas; and to parts of the posterior temporal lobe, the middle temporal area and the medial superior temporal area. Subcortical efferents of the striate cortex pass to the superior colliculus, pretectum and parts of the brain stem reticular formation. Projections to the striatum (notably the tail of the caudate nucleus), and to the pontine nuclei, are sparse. Geniculo- and claustrocortical projections are reciprocated by prominent descending projections, which arise in layer VI.

The second visual area (V2) occupies much of area 18 but is not coextensive with it. It contains a complete retinotopic representation of the visual hemifield, which is a mirror image of that in area 17, with the vertical meridian represented most posteriorly along the border between areas 17 and 18. The major ipsilateral corticocortical feedforward projection to V2 comes from V1. Feedforward projections from V2 pass to several other visual areas (and are reciprocated by feedback connections) including the third visual area (V3) and its various subdivisions (V3/V3d; VP/V3v; V3a); the fourth visual area (V4); areas in the temporal and parietal association cortices; and the frontal eye field. Thalamic afferents to V2 come from the lateral geniculate nucleus, the inferior and lateral pulvinar nuclei and parts of the intralaminar group of nuclei. Additional subcortical afferents are as for cortical areas in general. Subcortical efferents arise predominantly in layers V and VI. They pass to the thalamus, claustrum, superior colliculus, pretectum, brain stem reticular formation, striatum and pons. As for area 17, the callosal connections of V2 are restricted predominantly to the cortex, which contains the representation
of the vertical meridian.

The third visual area (V3) is a narrow strip adjoining the anterior margin of V2, probably still within area 18 of Brodmann. V3 has been subdivided into dorsal (V3/V3d) and ventral (VP/V3v) regions on the basis of its afferents from area V1, myeloarchitecture, callosal and association connections, and receptive field properties. The dorsal subdivision receives from V1, whereas the ventral does not. Functionally, the dorsal part shows less wavelength selectivity, greater direction selectivity and smaller receptive fields than does the ventral subdivision. Both areas receive a feedforward projection from V2, and are interconnected by association fibres. A further visual area, area V3a, lies anterior to the dorsal subdivision of V3. It receives afferent association connections from V1, V2, V3/V3d and VP/V3v, and has a complex and irregular topographic organization. All subdivisions project to diverse visual areas in the parietal, occipital and temporal cortices, including V4, and to the frontal eye fields.

The fourth visual area, V4, lies within area 19 anterior to the V3 complex. It receives a major ipsilateral feedforward projection from V2. Colour selectivity as well as orientation selectivity may be transmitted to V4 and bilateral damage causes achromatopsia. V4 is more complex than a simple colour discrimination area because it is also involved in the discrimination of orientation, form and movement. It sends a feedforward projection to the inferior temporal cortex and receives a feedback projection. It also connects with other visual areas that lie more dorsally in the temporal lobe, and in the parietal lobe. Thalamocortical connections are with the lateral and inferior pulvinar and the intralaminar nuclei. Other subcortical connections conform to the general pattern for all cortical areas. Callosal connections are with the contralateral V4 and other occipital visual areas.

A fifth visual area, V5 or the middle temporal area, is found in non-human primates towards the posterior end of the superior temporal sulcus. It receives ipsilateral association connections from areas VI, V2, V3 and V4, in a topographically organized way. Other lesser projections are received from widespread visual areas in the temporal and parieto-occipital lobes and from the frontal eye fields. V5 is primarily a movement detection or discrimination area, and contains a high proportion of movement-sensitive, direction-selective, cells. Feedforward projections go to surrounding temporal and parietal areas, and to the frontal eye field. Thalamic connections are with the lateral and inferior pulvinar and intralaminar group of nuclei. Other connections follow the general pattern of all neocortical areas.

Current concepts of visual processing in inferior temporal and temporoparietal cortices suggest that two parallel pathways (dorsal and ventral) emanate from the occipital lobe. The dorsal pathway, concerned primarily with visuospatial discrimination, projects from V1 and V2 to the
superior temporal and surrounding parietotemporal areas and ultimately to area 7a of the parietal cortex. The fourth visual area, V4, is a key relay station for the ventral pathway, which is related to perception and object recognition. Its connections pass sequentially along the inferior temporal gyrus in a feedforward manner, from V4 to posterior, intermediate and then anterior, inferior temporal cortices. Ultimately they feed into the temporal polar and medial temporal areas and so interface with the limbic system.
**LIMBIC LOBE**

The limbic lobe (Fig. 23.13) includes large parts of the cortex on the medial wall of the hemisphere, principally the subcallosal, cingulate and parahippocampal gyri. It also includes the hippocampal formation, which consists of the hippocampus proper (Ammon's horn or 'cornu ammonis'), the dentate gyrus, the subicular complex (subiculum, presubiculum, parasubiculum) and the entorhinal cortex (area 28). There is a close relationship between these phylogenetically old cortical structures and the termination of the olfactory tract in the frontal and medial temporal lobes.

![Fig. 23.13 Components of the limbic system (yellow). Medial aspect of the left cerebral hemisphere. The approximate locations of some Brodmann's areas are indicated.](image)

On the basis of emotional disturbances displayed by patients who presented with damage to the hippocampus and cingulate gyrus, Papez (1937) described a closed circuit (the Papez circuit), which linked the hippocampus with the cingulate cortex, via the mammillary bodies and anterior thalamus. He proposed that emotional expression is organized in the hippocampus, experienced in the cingulate gyrus and expressed via the mammillary bodies. The hypothalamus was considered to be the site where hippocampal processes gain access to the autonomic outflow that controls the peripheral expression of emotional states. The Papez circuit is now widely accepted to be involved with cognitive processes, including mnemonic functions and spatial short-term memory.

Later the term 'limbic system' became popular to describe the limbic lobe, together with closely associated subcortical nuclei including the amygdala, septum,
hypothalamus, habenula, anterior thalamic nuclei and parts of the basal ganglia.

The cingulate gyrus may be divided rostrocaudally into several cytoarchitectonically discrete areas. These are the prelimbic (area 32) and infralimbic (area 25) cortices, the anterior cingulate cortex (areas 23 and 24) and part of the posterior cingulate or retrosplenial cortex (area 29).

The cingulate gyrus, which is related to the medial surfaces of the frontal lobe, contains specific motor areas, and has extensive connections with neocortical areas of the frontal lobe. The cingulate gyrus on the medial surface of the parietal lobe has equally extensive connections with somatosensory and visual-association areas of the parietal, occipital and temporal lobes. These afferents to the cingulate gyrus are predominantly from neocortical areas on the lateral surface of the hemisphere. Within the cingulate cortex, most projections pass caudally, ultimately into the posterior parahippocampal gyrus. Through this system, afferents from widespread areas of association cortex converge upon the medial temporal lobe and hippocampal formation. There are other parallel stepwise routes to these targets through cortical areas on the lateral surface.

The cingulate gyrus is the area that shows the most consistent pain-evoked changes in synaptic activity related to regional cerebral blood flow (rCBF) as measured by either positron emission tomography (PET) or functional magnetic resonance imaging (fMRI) (Derbyshire et al 1997). It must be remembered that pain evokes a multidimensional response in the brain including cognitive, emotional, autonomic and motor components, and so it is not always possible to assign specific functions to parts of the brain that generate PET or fMRI signals in response to pain (Peyron et al 2000). However, in many experimental paradigms, a combination of signals from the cingulate gyrus, somatosensory area SII and the insula appears to be involved in the conscious appreciation of nociception and neuropathic pain.

The parahippocampal gyrus includes areas 27, 28 (entorhinal cortex), 35, 36, 48, 49 and temporal cortical fields. It has complex interconnections with the cingulate cortex and with the hippocampal formation. In monkeys, the infralimbic cortex (area 25) has been shown to project to areas 24a and 24b. Area 25 also has reciprocal connections with the entorhinal cortex. Projections between the paralimbic area 32 and the limbic cortex (anterior, retrosplenial and entorhinal cortex) are somewhat less prominent. Areas 24 and 29 are connected with the paralimbic posterior cingulate area 23. A pattern of cortical connections running outwards from the hippocampus, via the entorhinal cortex to the perirhinal cortex, caudal parahippocampal gyrus and posterior cingulate gyrus, is considered to be of great functional importance so far as the hippocampus is concerned. The parahippocampal gyrus projects to virtually all association areas of the cortex in primates and also provides the major funnel through which polymodal sensory inputs converge on the hippocampus.

Olfactory pathways

The organization of the olfactory system reflects its phylogenetically ancient lineage: afferent olfactory pathways proceed directly to the cerebral cortex, bypassing the thalamus, and its terminal fields are primitive cortical areas that are considered to be parts of the limbic system. Details of the relationship between the olfactory pathways and the limbic system are shown in Fig. 23.4.
The olfactory nerves arise from olfactory receptor neurones in the olfactory mucosa (see Ch. 32). The axons collect into numerous small bundles ensheathed by a population of unique glia and surrounded by layers of meninges, and enter the anterior cranial fossa by passing through the foramina in the cribiform plate of the ethmoid bone. They attach to the inferior surface of the olfactory bulb, which is situated at the anterior end of the olfactory sulcus on the orbital surface of the frontal lobe, and terminate in the bulb. Olfactory receptor neurones are continually replaced throughout life by differentiation of stem cells in the olfactory mucosa. The olfactory bulb is continuous posteriorly with the olfactory tract, through which the output of the bulb passes directly to the olfactory cortex.

There is a clear laminar structure in the olfactory bulb (Fig. 23.14). From the surface inwards the laminae are the olfactory nerve layer, glomerular layer, external plexiform layer, mitral cell layer, internal plexiform layer and granule cell layer. The olfactory nerve layer consists of the unmyelinated axons of the olfactory neurones. The continuous turnover of receptor cells means that axons in this layer are at different stages of growth, maturity or degeneration. The glomerular layer consists of a thin sheet of glomeruli where the incoming olfactory axons divide and synapse on terminal dendrites of secondary olfactory neurones, i.e. mitral, tufted and periglomerular cells. The external plexiform layer contains the principal and secondary dendrites of mitral and tufted cells. The mitral cell layer is a thin sheet composed of the cell bodies of mitral cells, each of which sends a single principal dendrite to a glomerulus, secondary dendrites to the external plexiform layer, and a single axon to the olfactory tract. It also contains a few granule cell bodies. The internal plexiform layer contains axons, recurrent and deep collaterals of mitral and tufted cells, and granule cell bodies. The granule cell layer contains the majority of the granule cells and their superficial and deep processes, together with numerous centripetal and centrifugal nerve fibres which pass through the layer.

Fig. 23.14 Organization of the olfactory bulb.
The principal neurones in the olfactory bulb are the mitral and tufted cells: their axons form its output via the olfactory tract. These cells are morphologically similar and most use an excitatory amino acid, probably glutamate or aspartate, as their neurotransmitter. The mitral cell spans the layers of the bulb, and receives the sensory input superficially at its glomerular tuft. The axons of mitral and tufted cells appear to be parallel output pathways from the olfactory bulb.

The main types of interneurones in the olfactory bulb are the periglomerular cells and granule cells. The majority of periglomerular cells are dopaminergic (cell group A15), but some are GABAergic: their axons are distributed laterally and terminate within extraglomerular regions. Granule cells are similar in size to periglomerular cells. Their most characteristic feature is the absence of an axon, and they therefore resemble amacrine cells in the retina. Granule cells have two principal spine-bearing dendrites which pass radially in the bulb: they appear to be GABAergic. The granule cell is likely to be a powerful inhibitory influence on the output neurones of the olfactory bulb.

Centrifugal inputs to the olfactory bulb arise from a variety of central sites. Neurones of the anterior olfactory nucleus and collaterals of pyramidal neurones in the olfactory cortex project to the granule cells of the olfactory bulb. Cholinergic neurones in the horizontal limb nucleus of the diagonal band of Broca, part of the basal forebrain cholinergic system, project to the granule cell layer and also to the glomerular layer. Other afferents to the granule cell layer and the glomeruli arise from the pontine locus coerules and the mesencephalic raphe nucleus.

The granule cell layer of the bulb is extended into the olfactory tract as scattered medium-sized multipolar neurones that constitute the anterior olfactory nucleus. Many centripetal axons from mitral and tufted cells relay in, or give collaterals to, the anterior olfactory nucleus; the axons from the nucleus continue with the remaining direct fibres from the bulb into the olfactory striae.

As the olfactory tract approaches the anterior perforated substance it flattens and splays out as the olfactory trigone. Fibres of the tract continue from the caudal angles of the trigone as diverging medial and lateral olfactory striae, which border the anterior perforated substance. The lateral olfactory stria follows the anterolateral margin of the anterior perforated substance to the limen insulae, where it bends posteromedially to merge with an elevated region, the gyrus semilunaris, at the rostral margin of the uncus in the temporal lobe. The lateral olfactory gyrus forms a tenuous grey layer covering the lateral olfactory stria: it merges laterally with the gyrus ambiens, part of the limen insulae. The lateral olfactory gyrus and gyrus ambiens form the prepiriform region of the cortex, passing caudally into the entorhinal area of the parahippocampal gyrus. The prepiriform and periamygdaloid regions and the entorhinal area (area 28) together make up the piriform cortex. The medial olfactory stria passes medially along the rostral boundary of the anterior perforated substance towards the medial continuation of the diagonal band of Broca. Together, they curve up on the medial aspect of the hemisphere, anterior to the attachment of the lamina terminalis.

The olfactory cortex receives a direct input from the olfactory bulb which arrives via the olfactory tract without relay in the thalamus. The largest cortical olfactory area is the piriform cortex. The anterior olfactory nucleus, olfactory tubercle, regions of the
entorhinal and insular cortex and amygdala also receive direct projections from the olfactory bulb.

The entorhinal cortex (Brodmann's area 28) is the most posterior part of the piriform cortex, and is divided into medial and lateral areas (areas 28a and 28b). The lateral parts receive fibres mainly from the olfactory bulb, and also from the piriform and periamygdaloid cortices.

Projections from the piriform olfactory cortex are widespread, and include the neocortex (especially the orbitofrontal cortex), thalamus (especially the medial dorsal thalamic nucleus), hypothalamus, amygdala and hippocampal formation.

**Hippocampal formation**

The hippocampal formation includes the dentate gyrus, hippocampus, subicular complex and entorhinal cortex.

The hippocampus lies above the subiculum and medial parahippocampal gyrus, forming a curved elevation, approximately 5 cm long, along the floor of the inferior horn of the lateral ventricle (Fig. 23.15). Its anterior end is expanded, and here its margin may present two or three shallow grooves that give a paw-like appearance, the pes hippocampi. The ventricular aspect is convex. It is covered by ependyma, beneath which fibres of the alveus converge medially on a longitudinal bundle of fibres, the fimbria of the fornix. Passing medially from the collateral sulcus, the neocortex of the parahippocampal gyrus merges with the transitional juxtalallocortex of the subiculum (Fig. 23.16). The latter curves superomedially to the inferior surface of the dentate gyrus, then laterally to the laminae of the hippocampus. This curvature continues, first superiorly, then medially above the dentate gyrus, and ends pointing towards the centre of the superior surface of the dentate gyrus. The dentate gyrus is a crenated strip of cortex related inferiorly to the subiculum, laterally to the hippocampus and, more medially, to the fimbria of the fornix (Fig. 23.16, Fig. 23.17). The form of the fimbria is quite variable, but medially it is separated from the crenated medial margin of the dentate gyrus by the fimbriodentate sulcus (Fig. 23.18). The hippocampal sulcus, of variable depth, lies between the dentate gyrus and the subicular extension of the parahippocampal gyrus. Posteriorly, the dentate gyrus is continuous with the gyrus fasciolaris and thus with the indusium griseum. Anteriorly, it is continued into the notch of the uncus, turning medially across its inferior surface, as the tail of the dentate gyrus (band of Giacomini), and vanishes on the medial aspect of the uncus (Fig. 23.17). The tail separates the inferior surface of the uncus into an anterior uncinate gyrus and posterior intralimbic gyrus.
Fig. 23.15 Dissection of the left cerebral hemisphere demonstrating structures of the limbic system. The body of the corpus callosum has been divided sagitally. The frontal, temporal and occipital lobes have been sectioned horizontally and their superior parts removed. The left lentiform complex and thalamus have been removed and the floor of the inferior horn of the lateral ventricle opened.

(Dissection by AM Seal; photograph by Kevin Fitzpatrick on behalf of GKT School of Medicine, London; figure enhanced by B. Crossman.)

Fig. 23.17  Basal aspect of the brain dissected to display the dentate gyri, uncus and fimbria on the left.
The trilaminar cortex of the dentate gyrus is the least complex of the hippocampal fields (Fig. 23.19). Its major cell type is the granule cell, found in the dense granule cell layer. Granule cells have unipolar dendrites that extend into the overlying molecular layer. The latter receives most of the afferent projections to the dentate gyrus, primarily from the entorhinal cortex (Fig. 23.20). The granule cell and molecular layers are sometimes referred to as the fascia dentata. The polymorphic layer, or hilus of the dentate gyrus, contains cells that give rise primarily to ipsilateral association fibres. They remain within the dentate gyrus and do not extend into other hippocampal fields.
Fig. 23.19  Coronal, thionin-stained section of the human hippocampal formation. Abbreviations: a, molecular layer of the dentate gyrus; b, granule cell layer of the dentate gyrus; c, plexiform layer of the dentate gyrus; CA1–3, fields of the hippocampus; d, stratum oriens layer of the hippocampus; DG, dentate gyrus; e, pyramidal cell layer of the hippocampus; EC, entorhinal cortex; f, stratum radiatum of the hippocampus; fim, fimbria; g, stratum lacunosum-molecular of the hippocampus; PaS, parasubiculum; PRC, perirhinal cortex; PrS, presubiculum; S, subiculum.

(By courtesy of D. Amaral.)
The hippocampus is trilaminar archicortex. It consists of a single pyramidal cell layer, with plexiform layers above and below it. It may best be divided into three distinct fields, CA1, CA2 and CA3 (Fig. 23.18, Fig. 23.19). Field CA3 borders the hilus of the dentate gyrus at one end, and field CA2 at the other. Field CA3 pyramidal cells are the largest in the hippocampus and receive the mossy fibre input from dentate granule cells on their proximal dendrites. The whole pyramidal cell layer in this field is about 10 cells thick. The border between CA3 and CA2 is not well marked. The CA2 field has the most compact layer of pyramidal cells. It completely lacks a mossy fibre input from dentate granule cells and receives a major input from the supramammillary region of the hypothalamus. Field CA1 is usually described as the most complex of the hippocampal subdivisions and its appearance varies along its transverse and rostrocaudal axes. The CA1/CA2 border is not sharp, and at its other end CA1
overlaps the subiculum for some distance. Approximately 10% of neurones in this field are interneurones.

It is common to describe several strata within the layers of the hippocampus. Starting from the ventricular aspect, these are the alveus (contains subicular and hippocampal pyramidal cell axons converging on the fimbria of the fornix); stratum oriens (mainly the basal dendrites of pyramidal cells and some interneurones); stratum pyramidalis; stratum lucidum (contains mossy fibres which make contact with the proximal dendrites of pyramidal cells in field CA3); and the stratum radiatum and stratum lacunosum-moleculare. The stratum lucidum is not as prominent in man as it is in other primates, and is not present in fields CA1 and CA2.

In the stratum radiatum and stratum oriens, CA3 and CA2 cells receive associational connections from other rostrocaudal levels of the hippocampus, as well as afferents from subcortical structures, e.g. the septal nuclei and supramammillary region. The projections from pyramidal cells of fields CA3 and CA2 to CA1, often called Schaffer collaterals, also terminate in the stratum radiatum and stratum oriens. The projections from the entorhinal cortex to the dentate gyrus (the perforant pathway) travel in the stratum lacunosum-moleculare, where they make synaptic contact en passant with the distal apical dendrites of hippocampal pyramidal cells.

The subicular complex is generally subdivided into subiculum, presubiculum and parasubiculum. The major subcortical projections of the hippocampal formation (to the septal nuclei, mammillary nuclei, nucleus accumbens and anterior thalamus), and to the entorhinal cortex, all arise from pyramidal neurones of the subicular complex. The subiculum consists of a superficial molecular layer containing apical dendrites of subicular pyramidal cells, a pyramidal cell layer, and a deep polymorphic layer. The presubiculum is medial to the subiculum and is distinguished by a densely packed superficial layer of pyramidal cells. It forms the boundary between the subicular complex as a whole and the entorhinal cortex. The cell layers deep to the parasubiculum are indistinguishable from the deep layers of the entorhinal cortex.

The entorhinal cortex (Brodman's area 28, Fig. 23.19) extends rostrally to the anterior limit of the amygdala. Caudally it overlaps a portion of the hippocampal fields. The more primitive levels of the entorhinal cortex (below the amygdala) receive projections from the olfactory bulb. More caudal regions do not generally receive primary olfactory inputs. The entorhinal cortex is divisible into six layers and is quite distinct from other neocortical regions. Layer I is acellular and plexiform. Layer II is a narrow cellular layer, which consists of islands of large pyramidal and stellate cells. These cell islands are a distinguishing feature of the entorhinal cortex. They form small bumps on the surface of the brain that can be seen by the naked eye (verrucae hippocampae), and provide an indication of the boundaries of the entorhinal cortex. Layer III consists of medium-sized pyramidal cells. There is no internal granular layer another classic feature of entorhinal cortex); in its place is an acellular region of dense fibres called the lamina dissecans, which is sometimes called layer IV. Layers III and V are apposed in regions where the lamina dissecans is absent. Layer V consists of large pyramidal cells five or six deep. Layer VI is only readily distinguishable from layer V close to the border with the perirhinal cortex. Its cells continue around the angular bundle (subcortical white matter deep to the subicular complex made up largely of perforant path axons) to lie beneath the pre- and parasubiculum.
Glutamate and/or aspartate appears to be the major excitatory transmitter in three pathways in the hippocampal formation, namely the perforant pathway (which arises in the entorhinal cortex and terminates primarily in the dentate gyrus); the mossy fibres, which run from the dentate granule cells to the pyramidal cells of the CA3 field; and in the Schaffer collaterals of CA3 pyramidal cells, which terminate on CA1 pyramidal cells.

GABAergic neurones are found in the deep portions of the granule cell layer in the dentate gyrus (basket cells). The highest concentration of GABA receptors is found in the molecular layer of the dentate gyrus. In the hippocampus proper, GABAergic cells are found mostly in the stratum oriens, but also in the pyramidal cell layer and stratum radiatum.

There are many peptide-containing neurones in the hippocampal formation. Granule cells in the dentate gyrus appear to contain the opioid peptide dynorphin, which is also present in mossy fibres running to the CA3 field. Enkephalin, or a related peptide, may be present in fibres arising in the entorhinal cortex. There is a dense plexus of somatostatin-immunoreactive fibres in the molecular layer of the dentate gyrus and also in the stratum lacunosum-moleculare of the hippocampus. The polymorphic layer of the dentate gyrus, stratum oriens of the hippocampus and the deep layers of the entorhinal cortex, all contain somatostatin-immunoreactive neurones. Vasoactive intestinal polypeptide (VIP)-immunoreactive neurones are plentiful in many hippocampal fields, especially in the superficial layers of the entorhinal cortex. Cells containing cholecystokinin (CCK)-immunoreactivity are found in the hilar region of the dentate gyrus, in all layers of the hippocampus, especially in the pyramidal cell layer, and also throughout the subicular complex and entorhinal cortex. There are also substantial plexuses of CCK-immunoreactive fibres in the stratum lacunosum-moleculare, subicular complex and entorhinal cortex. Hippocampal CCK-immunoreactive cells may give rise to extrinsic projections, e.g. to the lateral septum and medial mammillary nucleus, because CCK-immunoreactive fibres are found in the fimbria/fornix.

The medial septal complex and the supramammillary area of the posterior hypothalamus are the two major sources of subcortical afferents to the hippocampal formation. There are also projections from the amygdaloid complex and claustrum (to the subicular complex and entorhinal cortex), as well as monoaminergic projections from the ventral tegmental area, the mesencephalic raphe nuclei and the locus coeruleus. The noradrenergic and serotonergic projections reach all hippocampal fields, but are especially dense in the dentate gyrus.

The projections from the septal complex arise in the medial septal and vertical limb nuclei of the diagonal band. They travel via the dorsal fornix, fimbria, supracallosal striae and a ventral route through the amygdaloid complex. While these projections reach all hippocampal fields, the most prominent terminations are in the dentate gyrus, field CA3, presubiculum, parasubiculum and entorhinal cortex. Many of these medial septal/diagonal band neurones are GABAergic or cholinergic, and they form part of the topographically organized basal forebrain cholinergic system (cell groups Ch1 and Ch2).

Neurones in the supramammillary area also provide a significant innervation of the hippocampal formation. They arrive partly through the fornix and partly through a
ventral route, and terminate most heavily in the dentate gyrus, and fields CA2 and CA3 of the cornu ammonis.

All divisions of the anterior thalamic nuclear complex and associated lateral dorsal nucleus project to the hippocampal formation, and are directed predominantly to the subicular complex. Some midline thalamic nuclei, particularly the parataenial, central medial and reuniens nuclei, also project to the hippocampal formation, especially to the entorhinal cortex.

The human fornix contains more than a million fibres. Cells in the CA3 field project bilaterally to the lateral nucleus of the septal complex, via the precommissural fornix. They give rise to the Schaffer collaterals to CA1 cells and to the commissural projections to the contralateral hippocampus. Neurones in the subicular complex and entorhinal cortex give rise to projections to the nucleus accumbens and to parts of the caudate nucleus and putamen. The subicular complex gives rise to the major, postcommissural fibre system of the fornix. The presubiculum, in particular, projects to the anterior thalamic nuclear complex (anteromedial, anteroventral and laterodorsal nuclei). Both the subiculum and presubiculum provide the major extrinsic input to the mammillary complex. Both the lateral and the medial mammillary nuclei receive afferents from the subiculum complex.

Several fields in the temporal lobe neocortex, especially the parahippocampal gyrus, the dorsal bank of the superior temporal gyrus, the perirhinal cortex (Brodman's area 35) and the temporal polar cortex, together with the agranular insular cortex and posterior orbitofrontal cortex, project to the entorhinal cortex. Projections to the entorhinal cortex also arise from the dorsolateral prefrontal cortex (Brodman's areas 9, 10, 46), the medial frontal cortex (Brodman's areas 25, 32), the cingulate cortex (Brodman's areas 23, 24), and retrosplenial cortex. The subicular complex receives direct cortical inputs, e.g. from the temporal polar cortex, perirhinal cortex, parahippocampal gyrus, superior temporal gyrus and dorsolateral prefrontal cortex. The entorhinal cortex projects to the perirhinal cortex as well as to temporal polar cortex, caudal parahippocampal and cingulate gyri. In monkeys, the subicular complex also projects to a number of cortical areas, including perirhinal cortex, parahippocampal gyrus, caudal cingulate gyrus, medial frontal and medial orbitofrontal cortex.

**Septum**

The septum is a midline and paramedian structure (Fig. 23.13, Fig. 22.6). Its upper portion corresponds largely to the bilateral laminae of fibres, sparse grey matter and neuroglia, known as the septum pellucidum, which separates the lateral ventricles. Below this, the septal region is made up of four main nuclear groups: dorsal, ventral, medial and caudal. The dorsal group consists of the lateral septal nucleus, the ventral group consists of the lateral septal nucleus, the medial group contains the medial septal nucleus and the nucleus of the diagonal band of Broca, and the caudal group contains the fimbrial and triangular septal nuclei.

The major afferents to the region terminate primarily in the lateral septal nucleus. They include fibres carried in the fornix that arise from hippocampal fields CA3 and CA1 and the subiculum. There are also afferents arising from the preoptic area, anterior, paraventricular and ventromedial hypothalamic nuclei and the lateral hypothalamic...
area. The lateral septum receives a rich monaminergic innervation, including noradrenergic afferents from the locus coeruleus and medullary cell groups (A1, A2). It also receives serotonergic afferents from the midbrain raphe nuclei and dopaminergic afferents from the ventral tegmental area (A10).

Projections from the lateral septum run to the medial and lateral preoptic areas, anterior hypothalamus, supramammillary and midbrain ventral tegmental area, via the medial forebrain bundle. There is also a projection to the medial habenular nucleus and some midline thalamic nuclei via the stria medullaris thalami, which runs on the dorsomedial wall of the third ventricle. The projections from the habenula via the fasciculus retroflexus to the interpeduncular nucleus and adjacent ventral tegmental area in the midbrain provide a route through which forebrain limbic structures can influence midbrain nuclear groups.

A large proportion of the medial septal/diagonal band neurones are cholinergic or GABAergic. They project to the hippocampal formation and cingulate cortex.

**Amygdala**

The amygdala (amygdaloid nuclear complex) consists of lateral, central and basal nuclei that lie in the dorsomedial temporal pole, anterior to the hippocampus, close to the tail of the caudate nucleus (Fig. 23.13) and partly deep to the gyrus semilunaris, gyrus ambiens and uncinate gyrus (Fig. 23.4). Collectively the nuclei form the ventral, superior and medial walls of the tip of the inferior horn of the lateral ventricle. The amygdala is partly continuous above with the inferomedial margin of the claustrum. Fibres of the external capsule and substriatal grey matter, including the cholinergic magnocellular nucleus basalis (of Meynert), incompletely separate it from the putamen and globus pallidus. Laterally, it is close to the optic tract.

The lateral nucleus has dorsomedial and ventrolateral subnuclei. The central nucleus has medial and lateral subdivisions. The basal nucleus is commonly divided into a dorsal magnocellular basal nucleus, an intermediate parvicellular basal nucleus, and a ventral band of darkly staining cells usually referred to as the paralaminar basal nucleus, because it borders the white matter ventral to the amygdaloid complex. The accessory basal nucleus lies medial to the basal nuclear divisions and is usually divided into dorsal, magnocellular, and ventral, parvicellular, parts. The lateral and basal nuclei are often referred to collectively as the basolateral area (nuclear group) of the amygdaloid complex.

It has been suggested that the basolateral complex of nuclei (lateral, basal, accessory basal) shares several characteristics with the cortex, and that it may be considered as a quasi-cortical structure. Although it lacks a laminar structure, it has direct, often reciprocal, connections with adjacent temporal and other areas of cortex, and it projects to the motor or premotor cortex. It receives a direct cholinergic and non-cholinergic input from the magnocellular corticopetal system in the basal forebrain, and has reciprocal connections with the mediodorsal thalamus. The distribution of small peptidergic neurones in the basolateral nuclear complex, e.g. those containing neuropeptide-Y (NY), somatostatin (SOM) and CCK, are also similar in form and density to those found in the adjacent temporal lobe cortex. Projection neurones from this part of the amygdala appear to utilize, at least in part, the excitatory amino acids glutamate or aspartate as a transmitter. Moreover, they project to the ventral striatum.
rather than to hypothalamic and brain stem sites. Thus, it may be appropriate to consider this part of the amygdaloid complex as a polymodal cortex-like area, separated from the cerebral cortex by fibres of the external capsule.

The central nucleus is present through the caudal half of the amygdaloid complex. It lies dorsomedial to the basal nucleus and is divided into medial and lateral parts. The medial part, which contains larger cells than the lateral part, resembles the adjacent putamen. The medial and central nuclei appear to have an extension across the basal forebrain, as well as within the stria terminalis, which merges with the bed nucleus of the stria terminalis. This extensive nuclear complex is sometimes referred to as the ‘extended amygdala’ (Fig. 23.21). It can be considered as a macrostructure formed by the centromedial amygdaloid complex (medial nucleus, medial and lateral parts of the central nucleus), the medial bed nucleus of the stria terminalis, and the cell columns that traverse the sublenticular substantia innominata, which lies between them. It has been suggested that portions of the medial nucleus accumbens may be included in the extended amygdala.
A consistent feature of the intrinsic connections among amygdaloid nuclei is that they arise primarily in lateral and basal nuclei, and terminate in the central and medial nuclei, which suggests a largely unidirectional flow of information. In brief, the lateral nucleus projects to all divisions of the basal nucleus, accessory basal nucleus, paralaminar and anterior cortical nuclei, and less heavily to the central nucleus: it receives few afferents from other nuclei. The magnocellular, parvicellular and intermediate parts of the basal nucleus project to the accessory basal, central (especially the medial part) and medial nuclei, as well as to the periamygdaloid cortex and the amygdalohippocampal area. The accessory basal nucleus projects densely to the central nucleus, especially its medial division, as well as to the medial and cortical nuclei. Its major intra-amygdaloid afferents arise from the lateral nucleus. The medial nucleus projects to the accessory basal, anterior cortical and central nuclei as well as to the periamygdaloid cortex and amygdalohippocampal area, while afferents arise especially from the lateral nucleus. The intrinsic connections of the cortical nuclei are not very well understood. The posterior part of the cortical nucleus projects to the medial nucleus, but it has been difficult to differentiate this projection from that arising in the amygdalohippocampal area. The central nucleus projects to the anterior cortical nucleus and the various cortical transition zones. It forms an important focus for afferents from many of the amygdaloid nuclei, especially the basal and accessory basal nuclei, and it has major extrinsic connections.

The organization of the extensive subcortical and cortical connections of the amygdala are consistent with a role in emotional behaviour. It receives highly processed unimodal and multimodal sensory information from the thalamus, sensory and association cortices; olfactory information from the olfactory bulb and piriform cortex; visceral and gustatory information relayed via brain stem structures and the thalamus. Its projections reach widespread areas of the brain, including the endocrine and autonomic domains of the hypothalamus and brain stem.

**Afferent connections**

The heaviest brain stem projection to the amygdala arises in the peripeduncular nucleus. The parabrachial nuclei also project to the central nucleus. The amygdala receives a rich monoaminergic innervation. The noradrenergic projection arises primarily from the locus coeruleus, serotonergic fibres arise from the dorsal and, to some extent the median, raphe nuclei, and the dopaminergic innervation arises primarily in the midbrain ventral tegmental area (A10). The basal and parvicellular accessory basal nuclei, the amygdalohippocampal area and nucleus of the lateral olfactory tract receive a very dense cholinergic innervation arising from the magnocellular nucleus basalis of Meynert.

The amygdala has rich interconnections with allocortical, juxtallocortical and, especially, neocortical areas. In addition to direct projections from the olfactory bulb to the nucleus of the lateral olfactory tract, anterior cortical nucleus and the periamygdaloid cortex (piriform cortex), there are also associational connections between all parts of the primary olfactory cortex and these same superficial
amygdaloid structures. The amygdaloid complex has particularly extensive and rich connections with many areas of the neocortex in unimodal and polymodal regions of the frontal, cingulate, insular and temporal neocortices.

The anterior temporal lobe provides the largest proportion of the cortical input to the amygdala, predominantly to the lateral nucleus. Rostral parts of the superior temporal gyrus, which may represent unimodal auditory association cortex, project to the lateral nucleus. There are also projections from polymodal sensory association cortices of the temporal lobe, including perirhinal cortex (areas 35 and 36), the caudal half of the parahippocampal gyrus, the dorsal bank of the superior temporal sulcus, and both the medial and lateral areas of the cortex of the temporal pole.

The CA1 field of the hippocampus and adjacent subiculum, and possibly the entorhinal cortex, project to the amygdala, mainly to the parvicellular basal nucleus.

The rostral insula projects heavily to the lateral, parvicellular basal and medial nuclei. The caudal insula, which is reciprocally connected with the second somatosensory cortex, also projects to the lateral nucleus, thus providing a route by which somatosensory information reaches the amygdala. The caudal orbital cortex projects to the basal, magnocellular accessory basal and lateral nuclei. The medial prefrontal cortex projects to the magnocellular divisions of the accessory and basal nuclei.

**Efferent connections**

The central nucleus provides the major relay for projections from the amygdala to the brain stem and receives many of the return projections. It projects to the periaqueductal grey matter, ventral tegmental area, substantia nigra pars compacta, peripeduncular nucleus and tegmental reticular formation (midbrain); the parabrachial nuclei (pons); the nucleus of the solitary tract and the dorsal motor nucleus of the vagus (medulla).

The central nucleus is the major relay for amygdaloid projections to the hypothalamus. Amygdaloid fibres reach the bed nucleus of the stria terminalis primarily via the stria terminalis, but also via the ventral amygdalofugal pathway. In general, central and basal nuclei project to the lateral part of the bed nucleus, while medial and posterior cortical nuclei project to the medial bed nucleus. Anterior cortical and medial nuclei project largely to the medial preoptic area and anterior medial hypothalamus, including the paraventricular and supraoptic nuclei. There is a particularly prominent projection to the ventromedial and premammillary nuclei. The amygdala projects to the rostrocaudal extent of the lateral hypothalamus. The majority of the fibres originate in the central nucleus and run principally in the ventral amygdalofugal pathway and medial forebrain bundle.

There is a rich projection to the mediodorsal nucleus of the thalamus, which gives access to the prefrontal cortex, and also complements direct projections from the amygdala to the same cortical domain. The projection to the mediodorsal nucleus arises from most amygdaloid nuclei, but particularly from the lateral, basal and accessory basal nuclei and the periamygdaloid cortex. The major termination of amygdaloid afferents is in the medial, magnocellular part of the mediodorsal nucleus, especially rostrally. This part of the mediodorsal nucleus projects to the identical medial and orbital prefrontal cortical areas that receive amygdaloid afferents directly.
However, this projection to the mediodorsal nucleus is not reciprocated. The central and medial nuclei do not project to the mediodorsal nucleus, but to the midline nuclei, especially the nucleus centralis and nucleus reuniens.

The parvicellular division of the basal nucleus, magnocellular accessory basal nucleus (but not the magnocellular basal nucleus), and the central nucleus all project to basal forebrain cholinergic cell groups, notably the nucleus basalis of Meynert and the horizontal limb nucleus of the diagonal band.

The striatum, and particularly the nucleus accumbens, receives prominent projections from the amygdaloid complex. The basal and accessory basal nuclei are the most important contributors to this projection. The ventral striatum sends many fibres to the ventral pallidum, which in its turn projects to the mediodorsal nucleus of the thalamus. Thus, the ventral striatopallidal system provides a second route through which the amygdala can influence mediodorsal thalamic–prefrontal cortical processes.

The lateral, magnocellular accessory basal and parvicellular basal nuclei contribute the largest proportion of efferents to the hippocampal formation. The main projection is from the lateral nucleus to the rostral entorhinal cortex, but many fibres also terminate in the hippocampus proper and the subiculum. There appears to be marked polarity in amygdalohippocampal connections – the amygdala has a greater influence on hippocampal processes than vice versa.

The amygdaloid nuclear complex projects to widely dispersed neocortical fields. Amygdalocortical projections principally originate in the basal nucleus, and to a smaller extent in the lateral and cortical nuclei.

The amygdala projects to virtually all levels of the visual cortex in both temporal and occipital lobes. The largest component of these projections arises from the magnocellular basal nucleus. The amygdala also reciprocates projections to the auditory cortex in the rostral half of the superior temporal gyrus. Projections to the polymodal sensory areas of the temporal lobe generally reciprocate the amygdalopetal projections. Efferents from the lateral and accessory basal nuclei are directed to the temporal pole, particularly the medial perirhinal area.

The insular cortex is heavily innervated by the amygdaloid medial and anterior cortical nuclei. The orbital cortex and medial frontal cortical areas 24, 25 and 32, including parts of the anterior cingulate gyrus, also receive a heavy projection. Areas 8, 9, 45 and 46 of the dorsolateral prefrontal cortex, as well as the premotor cortex (area 6), receive a patchy innervation. The basal nucleus is an important source of these projections, which are augmented by contributions from the accessory basal (magnocellular and parvicellular divisions) and lateral nuclei.
WHITE MATTER OF CEREBRAL HEMISPHERE

The nerve fibres which make up the white matter of the cerebral hemispheres are categorized on the basis of their course and connections. They are either association fibres, which link different cortical areas in the same hemisphere; commissural fibres, which link corresponding cortical areas in the two hemispheres; or projection fibres, which connect the cerebral cortex with the corpus striatum, diencephalon, brain stem and the spinal cord.

ASSOCIATION FIBRES

Association fibres (Fig. 23.22, Fig. 23.23) may be either short association (arcuate or ‘U’) fibres, which link adjacent gyri, or long association fibres, which connect more widely separated gyri.

Fig. 23.22 The organization of the principal association fibres projected upon a sagittal section of the left cerebral hemisphere.
Short association fibres may be entirely intracortical. Many pass subcortically between adjacent gyri, some merely pass from one wall of a sulcus to the other.

Long association fibres are grouped into bundles, e.g. uncinate fasciculus, cingulum, superior longitudinal fasciculus, inferior longitudinal fasciculus and fronto-occipital fasciculus.

The uncinate fasciculus connects the motor speech (Broca's) area and orbital gyri of the frontal lobe with the cortex in the temporal pole. The fibres follow a sharply curved course across the stem of the lateral sulcus, near the anteroinferior part of the insula. The cingulum is a long, curved fasciculus, which lies deep to the cingulate gyrus. It starts in the medial cortex below the rostrum of the corpus callosum, follows the curve of the cingulate gyrus, enters the parahippocampal gyrus and spreads into the adjoining temporal lobe. The superior longitudinal fasciculus is the largest of the long association fasciculi. It starts in the anterior frontal region and arches back, above the insular area, contributing fibres to the occipital cortex (areas 18 and 19). It curves down and forwards, behind the insular area, to spread out in the temporal lobe. The inferior longitudinal fasciculus starts near the occipital pole. Its fibres, probably derived mostly from areas 18 and 19, sweep forwards, separated from the posterior horn of the lateral ventricle by the optic radiation and tapetal commissural fibres, and are distributed throughout the temporal lobe. The fronto-occipital fasciculus starts at the frontal pole. It passes back deep to the superior longitudinal fasciculus, separated from it by the projection fibres in the corona radiata. It lies lateral to the caudate nucleus near the central part of the lateral ventricle. Posteriorly, it fans out into the occipital and temporal lobes, lateral to the posterior and inferior horns of the lateral ventricle.
**COMMISSURAL FIBRES**

Commissural fibres cross the midline, many linking corresponding areas in the two cerebral hemispheres. By far the largest commissure is the corpus callosum. Others include the anterior, posterior and habenular commissures, and the commissure of the fornix.

**Corpus callosum**

The corpus callosum (Fig. 23.2, Fig. 23.24, Fig. 23.25; see Fig. 22.2) is the largest fibre pathway of the brain. It links the cerebral cortex of the two cerebral hemispheres, and it roofs much of the lateral ventricles. It forms an arch approximately 10 cm long, with an anterior end approximately 4 cm from the frontal poles and a posterior end approximately 6 cm from the occipital poles. Its anterior portion is known as the genu. This recurves posteroinferiorly in front of the septum pellucidum, then diminishes rapidly in thickness and is prolonged to the upper end of the lamina terminalis as the rostrum. The trunk of the corpus callosum arches back and is convex above. It ends posteriorly in the expanded splenium, which is its thickest part.
Fig. 23.24  The superior aspect of the corpus callosum revealed by partial removal of the cerebral hemispheres.
The median region of the trunk of the corpus callosum forms the floor of the great longitudinal fissure. Here, it lies close to the anterior cerebral arteries and the lower border of the falx cerebri, which may contact it behind. On each side, the trunk is overlapped by the cingulate gyrus, from which it is separated by the callosal sulcus. The inferior surface of the corpus callosum is concave in its long axis: it is attached to the septum pellucidum anteriorly and fused with the fornix and its commissure posteriorly.

The superior surface of the callosal trunk (Fig. 23.24) is covered by a thin layer of grey matter, the indusium griseum. This extends anteriorly around the genu and then continues into the paraterminal gyrus on the inferior aspect of the rostrum. It contains narrow longitudinal bundles of fibres on each side, the medial and lateral longitudinal striae. Posteriorly, the indusium griseum is continuous with the dentate gyrus and hippocampus through the gyrus fasciolaris (Fig. 23.25).

The splenium of the corpus callosum overhangs the posterior ends of the thalami, the pineal gland and tectum, but is separated from them by several structures. On each side the crus of the fornix and gyrus fasciolaris curve up to the splenium. The crus continues forwards on the inferior surface of the callosal trunk, but the gyrus fasciolaris skirts above the splenium, then rapidly diminishes into the indusium griseum. The tela choroidea of the third ventricle advances below the splenium through the transverse fissure, and the internal cerebral veins emerge between its two layers to form the great cerebral vein. Posteriorly the splenium is near the tentorium cerebelli, great cerebral vein and the start of the straight sinus.

Nerve fibres of the corpus callosum radiate into the white matter core of each hemisphere, thereafter dispersing to the cerebral cortex. Commissural fibres forming the rostrum extend laterally, below the anterior horn of the lateral ventricle, connecting the orbital surfaces of the frontal lobes. Fibres in the genu curve forwards, as the forceps minor, to connect the lateral and medial surfaces of the frontal lobes. Fibres of the trunk pass laterally, intersecting with the projection fibres of the corona radiata to connect wide neocortical areas of the hemispheres. Fibres of the trunk and splenium, which form the roof and lateral wall of the posterior horn and the lateral wall of the
inferior horn of the lateral ventricle, constitute the tapetum. The remaining fibres of the splenium curve back into the occipital lobes as the forceps major.

Interhemispheric connections through the corpus callosum do not all represent a simple linking of loci in one hemisphere with the same loci in the other. In areas containing a clear representation of a contralateral sensorium (e.g. body surface, visual field), only those areas that are functionally related to midline representation are linked to the contralateral hemisphere. This is most clearly seen for the visual areas, where the cortex containing the representation of each midline retinal zone is linked to its counterpart on the contralateral side. A similar arrangement is seen in somatic areas, where the trunk representation is callosally linked, but the peripheral limb areas (hand and foot) are not.

Connections that link the same, or similar, areas on each side are termed homotopic connections. The corpus callosum also interconnects heterogeneous cortical areas on the two sides (heterotopic connections). These may serve to connect functionally similar, but anatomically different, loci in the two hemispheres, and/or to connect functional areas in one hemisphere with regions that are specialized for a unilaterally confined function in the other.

**Anterior commissure**

The anterior commissure is a compact bundle of myelinated nerve fibres which crosses anterior to the columns of the fornix and is embedded in the lamina terminalis, where it is part of the anterior wall of the third ventricle (Fig. 23.13). In sagittal section it is oval, its long (vertical) diameter is approximately 1.5 mm. Laterally it splits into anterior and posterior bundles. The smaller anterior bundle curves forwards on each side to the anterior perforated substance and olfactory tract. The posterior bundle curves posterolaterally on each side in a deep groove on the anteroinferior aspect of the lentiform complex, and subsequently fans out into the anterior part of the temporal lobe, including the parahippocampal gyrus. Areas thought to be connected via commissural fibres include: the olfactory bulb and anterior olfactory nucleus; the anterior perforated substance, olfactory tubercle and diagonal band of Broca; the prepiriform cortex; the entorhinal area and adjacent parts of the parahippocampal gyrus; part of the amygdaloid complex (especially the nucleus of the lateral olfactory stria); the bed nucleus of the stria terminalis and the nucleus accumbens; the anterior regions of the middle and inferior temporal gyri.
PROJECTION FIBRES

Projection fibres connect the cerebral cortex with lower levels in the brain and spinal cord. They include large numbers of both corticofugal and corticopetal projections. Corticofugal projection fibres converge from all directions to form the dense subcortical white matter mass of the corona radiata (Fig. 23.26). Large numbers of fibres pass to the corpus striatum and the thalamus, intersecting commissural fibres of the corpus callosum en route. The corona radiata is continuous with the internal capsule, which contains the majority of the cortical projection fibres.

Fig. 23.26 A series of dissections of the left cerebral hemisphere at progressively deeper levels to demonstrate the relationships of the internal capsule. A, intact brain; B, cortical gyri of the insula exposed by removal of the frontal, temporal and parietal opercula; C, removal of the insular cortex, extreme capsule, claustrum and external capsule to expose the lateral aspect of the putamen; D, removal of the lentiform complex to display fibres of the internal capsule; E, removal of part of the temporal lobe to show the internal capsule fibres converging on the crus cerebri of the midbrain; F, removal of the optic tract, and superficial dissection of the pons and upper medulla, emphasizing the continuity of the corona radiata, internal capsule, crus cerebri, longitudinal pontine fibres and the medullary pyramid.
**Internal capsule**

In horizontal cerebral sections the internal capsule appears as a broad white band, with a lateral concavity, which accommodates the lentiform complex (Fig. 23.27, Fig. 23.28, Fig. 23.29). It has an anterior limb, genu, posterior limb, and retrolenticular (retrolentiform) and sublenticular (sublentiform) parts. Both anterior and posterior limbs are medial to the lentiform complex. The head of the caudate nucleus is medial to the anterior limb, and the thalamus is medial to the posterior limb. Cortical efferent fibres of the internal capsule continue to converge as they descend. Fibres derived from the frontal lobe tend to pass posteromedially, while temporal and occipital fibres pass anterolaterally. Many, but not all, corticofugal fibres pass into the crus cerebri of the ventral midbrain. Here, corticospinal and corticobulbar fibres are located in the middle half of the crus. Frontopontine fibres are located medially, whereas corticopontine fibres from temporal, parietal and occipital cortices are found laterally.
Fig. 23.28  Horizontal section of the brain through the frontal and occipital poles of the cerebral hemispheres. (Figure enhanced by B. Crossman.)
The anterior limb of the internal capsule contains frontopontine fibres, which arise from the cortex in the frontal lobe. They synapse with cells in the pontine nuclei. Axons of these cells enter the opposite cerebellar hemisphere through the middle cerebellar peduncle. Anterior thalamic radiations interconnect the medial and anterior thalamic nuclei and various hypothalamic nuclei and limbic structures with the frontal cortex.

The genu of the internal capsule is usually regarded as containing corticobulbar fibres, which are mainly derived from area 4 and terminate mostly in the contralateral motor nuclei of cranial nerves. Anterior fibres of the superior thalamic radiation, between the thalamus and cortex, also extend into the genu.

The posterior limb of the internal capsule includes the corticospinal tract. The fibres concerned with the upper limb are anterior. More posterior regions contain fibres representing the trunk and lower limbs. Other descending axons include frontopontine fibres, particularly from areas 4 and 6, and corticorubral fibres, which connect the frontal lobe to the red nucleus. Most of the posterior limb also contains fibres of the superior thalamic radiation (the somaesthetic radiation) ascending to the postcentral gyrus.

The retrolenticular part of the internal capsule contains parietopontine, occipitopontine, and occipitotectal fibres. It also includes the posterior thalamic radiation and the optic radiation, and interconnections between the occipital and parietal lobes and caudal parts of the thalamus, especially the pulvinar.

The optic radiation arises in the lateral geniculate body. It sweeps backwards, intimately related to the superolateral aspect of the inferior horn and the lateral aspect of the posterior horn of the lateral ventricle, from which it is separated by the tapetum.

The sublenticular part of the internal capsule contains temporopontine and some parietopontine fibres, the auditory radiation from the medial geniculate body to the superior temporal and transverse temporal gyri (areas 41 and 42), and a few fibres that connect the thalamus with the temporal lobe and insula. Fibres of the auditory
radiation sweep anterolaterally below and behind the lentiform complex to reach the cortex.
CEREBRAL ASYMMETRY

The two human cerebral hemispheres are not simply mirror images of each other. Much information on the lateralization of cerebral function has come from studying patients in whom the corpus callosum had been divided (commissurotomy) as a treatment for intractable epilepsy, and from those rare individuals who lack part, or all, of their corpus callosum. Commissurotomy produces the ‘split-brain’ syndrome, which has provided evidence supporting the notion that abilities or functions are predominantly associated with one or other hemisphere. Knowledge of such lateralization of function has been advanced more recently by functional brain imaging techniques such as positron emission tomography (PET).

The left hemisphere usually prevails for verbal and linguistic functions, for mathematical skills and for analytical thinking. The right hemisphere is mostly non-verbal. It is more involved in spatial and holistic or ‘Gestalt’ thinking, in many aspects of musical appreciation, and in some emotions. Memory also shows lateralization. Thus, verbal memory is primarily a left hemisphere function, while non-verbal memory is represented in the right hemisphere. These asymmetries are relative, not absolute, and vary in degree according to the function and individual concerned. Moreover, they apply primarily to right-handed men. Those men with left-hand preference, or mixed handedness, make up a heterogeneous group, which (as an approximation) shows reduced or anomalous lateralization, rather than a simple reversal of the situation in right-handers. For example, speech representation can occur in either or both hemispheres. Women show less functional asymmetry, on average, than men.

Certain cerebral anatomical asymmetries are apparent at both the macroscopic and histological levels. One of the most notable is in the planum temporale, which is usually larger on the left than the right side. Subtle asymmetries in the superior temporal lobe have been demonstrated in terms of overall size and shape, sulcal pattern, cytoarchitecture and at the neuronal level. It seems reasonable to assume that these differences underlie some of the functional asymmetry for language representation.

Asymmetries in areal size, cytoarchitecture or neurocytology occur elsewhere in the cerebral cortex as well as subcortically. For example, many brains have a wider right frontal pole and a wider left occipital pole. Brodmann's area 45 in the inferior frontal lobe, corresponding to Broca's area, contains a population of large pyramidal neurones that are found only on the left side. The cortical surface surrounding the central sulcus is larger in the left hemisphere, especially in the areas containing the primary somatosensory and motor maps of the arm, suggesting that one cerebral manifestation of hand preference is a larger amount of neural circuitry in the relevant parts of the cortex. Histological asymmetries are also found in areas that are not
usually considered to be closely related either to language or handedness. The left entorhinal cortex has significantly more neurones than the right.
NEUROPSYCHOLOGICAL FUNCTIONS

The neuropsychological functions of perception, spatial analysis, learned skilled movement, language, memory, problem solving (all executive functions) and emotion, are organized within the cerebral hemispheres (Fig. 23.30).

The organization of neuropsychological functions is highly localized and involves the association areas of the neocortex and the limbic system. The parietal association areas are concerned with the perceptual recognition of objects by kinaesthetic and visual stimuli, and the visuo-spatial orientation of the body and its parts in space. Large focal lesions (particularly of the right cerebral hemisphere) and bilateral lesions (e.g. in Alzheimer's disease), lead to visual disorientation in space, with an inability to navigate the environment, locate objects, and dress in relationship to body parts. Acute focal lesions (especially of the right cerebral hemisphere) lead to neglect of the body and space in the opposite side of corporeal and visual space (neglect). Failure of recognition of objects by touch or vision, represents tactile or visual agnosia. The
parietal-temporal cortical connections are particularly important for visual object recognition and lesions lead to an inability to identify, copy, or match, objects (apperceptive visual agnosia). The anterior superior parietal lobes and the related connections with the pre-motor areas, including the supplementary motor areas, are concerned in the execution of skilled movements through development and experience (praxis). Lesions of these areas lead to contralateral loss of skilled movements of the face, mouth and limbs (ideomotor apraxia).

The anterior temporal neocortex (middle and inferior temporal gyri) is concerned in ascribing meaning to perceptual stimuli. Bilateral lesions of these areas (e.g. in semantic dementia) leads to loss of recognition of words and percepts. Unilateral lesions in the left hemisphere particularly affect word meaning and naming (semantic or trans-cortical aphasia), whereas lesions of the right hemisphere lead primarily to loss of recognition of visual percepts (associative visual agnosia) and faces (prosopagnosia), and objects can be copied or matched but not identified for meaning or name.

The pre-motor areas (frontal association cortex, parietal and temporal association cortex) combine to form the ‘language area’ in the cortex that surrounds the lateral fissure in the left dominant hemisphere. Focal lesions of the language area lead to breakdown in verbal communication (aphasia) and loss of the ability to read (alexia), write (agraphia), and calculate (acalculia). The aphasis syndromes of Broca, conduction and Wernicke, correspond to lesions within the frontal, parietal, and temporal cortical areas, respectively. Lesions of the parietal cortex immediately posterior to the language area (angular gyrus) can lead to alexia, agraphia and acalculia, in the absence of aphasia.

The pre-frontal association cortex and its connections with the limbic system, and in particular, with the amygdala, are essential for problem solving behaviour (executive functions) and the affective motivational aspects of behaviour. Bilateral lesions of these areas (e.g. in frontotemporal dementia) lead to the ‘frontal lobe syndrome’, in which there is a radical change in personality, with loss of reason, judgement, and insight, together with loss of personal and social feelings (sympathy and empathy). The restricted involvement of the orbital frontal areas and limbic connections leads to over-activity and disinhibition (pseudo psychopathic behaviour). Spread of lesions into the dorsolateral surface of the pre-frontal area leads to an inert, apathetic, state (pseudo depression). Unilateral focal lesions of the pre-frontal areas are not usually associated with obvious cognitive or behavioural change.

The limbic allocortex and its connections comprising the Papez circuit (hippocampus, mammillary body, anterior nucleus of the thalamus, and cingulate gyrus) are responsible for the laying down of autobiographical (episodic) memory. Bilateral lesions (e.g. in Alzheimer's disease) or following alcoholic encephalopathy (Korsakoff psychosis) lead to the loss of ability to learn new information (anterograde amnesia) or remember experiences in the relatively recent past (retrograde amnesia). However, perceptual information about the world and language (semantic memory) are preserved, because the temporal neocortical association areas are spared.

Patients with chronic epilepsy, who have undergone surgical section of the corpus callosum in order to relieve their seizures, portray few difficulties under normal circumstances. However, when these ‘split brain’ patients undergo psychological
testing, the two halves of the brain appear to behave relatively autonomously, e.g. visual information directed to the right cerebral hemisphere alone does not evoke a verbal response, and consequently individuals cannot name objects or read words solely presented to the left visual field. Destruction of the splenium of the corpus callosum and its connections to the left occipital cortex, either by stroke or tumour, leads to the posterior disconnection syndrome of ‘alexia without agraphia’. Such individuals speak and write without difficulty but cannot understand written material (alexia). Disconnection of visual processes in the right hemisphere from the verbal processes of the dominant left cerebral hemisphere is thought to explain the syndrome.

CHAPTER 24 – Development of the nervous system

The entire nervous system and the special sense organs originate from three sources, each derived from specific cell populations of the early epiblast termed neural ectoderm. The first source to be clearly delineated is the neural plate, which gives rise to the central nervous system, the somatic motor nerves and the preganglionic autonomic nerves. The second source is from cells at the perimeter of the neural plate, neural crest cells, which remove themselves by epithelial/mesenchymal transition from the plate and migrate away just prior to its fusion into a neural tube. These cells give rise to the majority of the neurones and glia of the peripheral nervous system, i.e. the somatic sensory nerves, the somatic and autonomic ganglia, postganglionic autonomic nerves and suprarenal and chromaffin cells. They also give rise to significant mesenchymal populations in the head. The third source is from ectodermal placodes, which are focal thickening of the ectoderm covering the embryonic head. They contribute cells to the cranial sensory neurones, and form the olfactory epithelia, the epithelia of the inner ear and, by a non-neuronal contribution, the lens of the eye.

NEURULATION

Primary neurulation begins at stage 9 and is completed during stage 12 (Fig. 24.1). The process, although continuous spatially and temporally, has been envisaged as four stages. It begins with local elongation of the ectoderm cells in a midline zone of the embryonic disc and their reorganization into a pseudostratified epithelium, the neural plate. This is followed by reshaping and bending of the neural plate into a neural groove which subsequently closes to form into a neural tube bidirectionally from the midportion to its cranial and caudal ends. A continuous surface ectoderm forms dorsal to the tube.
Primary neurulation depends on cellular changes within the neural plate: in the trunk it may also involve movements of the paraxial mesenchyme. There is fusion initially of the surface ectoderm followed by fusion of the neural ectoderm. The neural ectodermal cells become elongated and then wedge-shaped. It has been suggested that the forces needed to shape the neural tube are intrinsic to the cells of the neur ectoderm. When the neural tube is closing, its walls consist of a single layer of columnar neural epithelial cells, whose extremities abut on internal and external limiting membranes. The columnar cells increase in length and develop numerous
longitudinally disposed microtubules. The borders of their luminal ends are firmly attached to adjacent cells by junctional complexes, and the cytoplasmic aspect of the complexes are associated with a dense paraluminal web of microfilaments. The nuclei assume basal positions which, together with the disposition of organelles, impart a slight wedge conformation on some of the cells, and create a hinge point.

The position of hinge points within the neural plate confers different characteristics on the formed neural tube. With a median hinge point, the neural folds remain relatively straight and the tube in this position has a slit-shaped lumen: this can be seen from the initial region of fusion rostralward. If dorsolateral hinge points are added, the resulting neural tube is rhombic, and the hinge points describe the position of the sulcus limitans. If all the neuroepithelial cells exhibit some apical narrowing, then the resulting tube has a circular lumen. The rostral slit-shaped profile of the neural tube may depend more on support from adjacent tissues than the caudal end of the tube, where neurulation is generated by the neuroepithelium. The transition from primary to secondary neurulation (see below) continues the production of a neural tube with a circular lumen.

Fusion of the neural tube starts in embryos with 4–6 somites, at the level of somites 1 and 2, forming the future rhombencephalon. The tube closes caudally and rostrally, forming sequentially cervical and thoracic cord regions, then mesencephalic and prosencephalic brain regions. Rostrally two sites of fusion can be seen. The initial fusion termed \( \alpha \), or the dorsal lip of the rostral neuropore, proceeds caudorostrally. A second site, termed \( \beta \), or the terminal lip of the rostral neuropore, closes from the rostral end of the neural plate and proceeds rostrocaudally (O'Rahilly & Müller 2002). Closure of these lips of the rostral neuropore is completed when 19–20 pairs of somites are present. Caudal neuropore closure starts when approximately 29 somites are present and the site of closure corresponds to the level of the future somite 31 (the level of the future second sacral vertebra) (O'Rahilly & Müller 2004).

Secondary neurulation starts from the closure of the caudal neuropore at stage 12 and ends at about stage 17; it is the process by which the caudal portion of the neural tube is formed in the absence of a neural plate. At the time of caudal neuropore closure, the caudal midline cells are generically termed the caudal eminence. A specific population of mesenchymal cells, the caudoneural hinge or junction, shares the same molecular markers as the primitive node. These cells aggregate at the midline and undergo mesenchymal/epithelial transformation, producing a cellular cylinder that is contiguous with the caudal end of the neural tube. Further elongation of the caudal neural tube involves cavitation of the neural cylinder. Neural crest cells delaminate from the dorsal surface of the cylinder in a rostrocaudal direction and concurrently, the paraxial mesenchyme undergoes somitogenesis.

**EARLY BRAIN REGIONS**

Prior to the closure of the neural tube, the neural folds become considerably expanded in the head region; the first indication of a brain and its major divisions can be seen at stage 10 (Fig. 24.2). Regional expansions, prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain), have been called the three primary cerebral vesicles, although the term ‘vesicle’ in this context has been considered inappropriate to describe localized accelerations of growth in the wall of the brain. As the neural tube closes, the neural wall appears to form a series of ridges
and depressions perpendicular to its long axis. These transient repeating segments are termed primary neuromeres, and initially six can be identified: the prosencephalon, mesencephalon and four subdivisions of the rhombencephalon, rhombomeres A, B, C and D. The primary neuromeres themselves become subdivided during stages 10, 11 and 12 and a total of 16 secondary neuromeres have been identified. The prosencephalon gives rise to the telencephalon, diencephalon 1 (D1) and diencephalon 2 (D2), which has three subdivisions. The mesencephalon is subdivided into mesencephalon 1 (M1) and mesencephalon 2 (M2). The rhombencephalon is subdivided into the isthmus rhombencephali and rhombomeres 1–8; the original rhombomere A gives rise to secondary rhombomeres 1, 2 and 3; rhombomere B gives rise to secondary rhombomere 4; rhombomere C gives rise to secondary rhombomeres 5, 6 and 7; and rhombomere D gives rise to secondary rhombomere 8 (O'Rahilly & Müller 1999). As the rhombencephalon grows the rhombomeric boundaries become less distinct. With the early appearance of the cerebellum from the isthmus rhombencephali and rhombomere 1, the rhombocephalon is traditionally divided into the metencephalon, which extends to about rhombomere 3, and the myelencephalon, which extends to the spinomedullary junction. A summary of the derivative of the cerebral regions is given in Table 24.1 on page 376.
Fig. 24.2 The primary brain regions, neuromeres, and their expansion during neurulation.

The elongation of the brain occurs at the same time as the appearance of three
Flexures, which also appear prior to the closure of the neural tube; two are concave ventrally and one concave dorsally. During stages 13 and 14 the brain bends at the mesencephalon (mesencephalic flexure) so that the prosencephalon bends in a ventral direction around the cephalic end of the notochord and foregut until its floor lies almost parallel with that of the rhombencephalon (Fig. 24.3). A bend also appears at the junction of the rhombencephalon and spinal cord (cervical flexure). This increases from the fifth to the end of the seventh week, by which time the rhombencephalon forms nearly a right angle to the spinal cord. However, after the seventh week, extension of the head takes place and the cervical flexure diminishes and eventually disappears. The third bend, the pontine flexure, is directed ventrally between the metencephalon and myelencephalon. It does not substantially affect the outline of the head. In this region, the roof plate thins until it is composed only of a single layer of cells and pia mater, the tela choroidea. The flexure of the neural tube at this point produces a rhombic shape in the roof which later forms the medullary velum.

Fig. 24.3 Developing human brains indicating formation of the mesencephalic, cervical and pontine flexures, lateral views. A, Human embryo, 9 mm long. B, Human embryo, approximately 10.2 mm long. C, Human embryo, 13.6 mm long. The roof of the rhombencephalon has been removed in each case.
EARLY CELLULAR ARRANGEMENT OF THE NEURAL TUBE

Histologically the early neural tube is composed of a pseudostratified neuroepithelium. It extends from the inner aspect of the tube to the outer limiting basal lamina and the surrounding pia mater. The epithelium contains stem cells which will give rise to populations of neuroblasts and glioblasts. A population of radial glia differentiates very early and provides a scaffold for later cells to follow. As development proceeds, three zones or layers develop (Figs 24.4–24.6). These are an internal ventricular zone (variously termed the germinal, primitive ependymal or matrix layer), in which mitosis occurs, and which contains the nucleated parts of the columnar cells and rounded cells undergoing mitosis; a middle, mantle zone (also termed the intermediate zone) which contains the migrant cells from the divisions occurring in the ventricular zone; and an outer, marginal zone, which initially consists of the external cytoplasmic processes of the radial glia. The latter is soon invaded by tracts of axonal processes which grow from neuroblasts developing in the mantle zone, together with varieties of non-neuronal cells (glial cells and later vascular endothelium and perivascular mesenchyme). For further development of these layers see pages 368–369.
Fig. 24.4 Transverse section through the developing spinal cord of a 4-week-old human embryo.

Fig. 24.5 Early development of the neural tube: three layers can be delineated in the spinal cord and brain stem.
At first the neural tube caudal to the brain is oval in transverse section and its lumen is narrow and slit-like (Fig. 24.4). The original floor plate and the dorsal site of fusion of the tube initially contain non-neural cells. With cellular proliferation, the lateral walls thicken and the lumen, now the central canal, widens in its dorsal part and is somewhat diamond-shaped on cross-section (Fig. 24.6). The widening of the canal is associated with the development of a longitudinal sulcus limitans on each side which divides the ventricular and mantle (intermediate) zones in each lateral wall into a ventrolateral lamina or basal plate and a dorsolateral lamina or alar plate respectively. This separation underlies a fundamental functional difference.

Throughout the neural tube there is a generic pattern in the position of the neurones which is specified by the juxtaposition of the notochord to the neural tube. Experimental lateral or dorsal grafting of a notochord results in the induction of a floor plate overlying the grafted notochord and the induction of ectopic motor neurones dorsally. Similarly, lateral or dorsal grafts of a floor plate also result in the induction of a new floor plate overlying the graft and the induction of ectopic dorsal motor neurones. Removal of the notochord results in the elimination of the floor plate and the motor neurones and the differentiation of dorsal cell types in the ventral region of the cord (Fig. 24.7).
Fig. 24.7  A–B. Successive stages in the development of the neural tube and spinal cord. A. The neural plate consists of epithelial cells. Cells in the midline of the neural plate are contacted directly by the notochord. More lateral regions of the neural plate overlie the paraxial mesenchyme (not shown). B. During neurulation, the neural plate bends at its midline and this elevates the lateral edges of the plate as the neural folds. Contact between the midline of the neural plate and the notochord is maintained at this stage. C. The neural tube is formed when the dorsal tips of the neural folds fuse. Cells in the region of fusion form the roof plate which is a specialized group of dorsal midline cells. D. Cells at the ventral midline of the neural tube retain proximity to the notochord and differentiate into the floor plate. After neural tube closure neuroepithelial cells continue to proliferate and eventually differentiate into defined classes of neurones at different dorsoventral positions within the spinal cord. For example, sensory relay, commissural and other classes of dorsal neurones differentiate near to the roof plate, and motor neurones differentiate ventrally near the floor plate, which by this time is no longer in contact with the notochord. E–H. A summary of the results obtained from experiments in chick embryos in which a notochord or floor plate is grafted to the dorsal midline of the neural tube or where the notochord is removed before neural tube closure. E. The normal condition, showing the ventral location of motor neurones and the dorsal location of sensory relay neurones. F. Dorsal grafts of a notochord result in the induction of a floor plate in the dorsal midline and ectopic dorsal motor neurones. G. Dorsal grafts of a floor plate induce a new floor plate in the dorsal midline and ectopic dorsal motor neurones. H. Removal of the notochord results in the elimination of the floor plate and the motor neurones and the expression of dorsal cells types in the ventral region of the spinal cord.

The basal plate is normally concerned predominantly with motor function, and contains the cell bodies of motor neurones of the future anterior and lateral grey columns. The alar plate receives sensory inflow from external dorsal root ganglia. Motor and sensory axons combine to form the mixed nerves.
FAILURE OF NEURULATION

Failure of neurulation produces the conditions of craniorachischisis totalis (where the entire neural tube is unfused in the dorsal midline), cranioceliosis or anencephaly (where the neural tube is fused dorsally to form the spinal cord but is not fused dorsally in the brain), and spina bifida (where local regions of the spinal neural tube are unfused, or there is failure of formation of the vertebral neural arches). (Fig. 24.8; see also Ch. 44). Anencephalic fetuses display severe disturbances in the shape, position and ossification of the basichondrocranium and in the course of the intracranial notochord and so the condition is more complicated than 'simply' a failure of neural tube fusion.

Fig. 24.8 Defects caused by failure of neural tube formation. A, Total failure of neurulation. B, Failure of rostral neurulation. C, Failure of caudal neurulation.
NEURAL CREST

The neuronal populations of the early epiblast become arranged in the medial region of the embryonic disc as the neural plate. Laterally, neural folds or crests indicate the transitional region between neural and surface ectoderm. Along most of the neuraxis the cells at the tips of the neural folds undergo an epithelial/mesenchyme transformation. They acquire migratory properties and leave the epithelium just prior to its fusion with the contralateral fold in the dorsal midline. The migratory cells so formed are collectively termed the neural crest. Cells within the rostral prosencephalic neural fold and smaller populations of cells in bilateral sites lateral to the early brain do not form migratory neural crest cells but remain within the surface epithelium as ectodermal placodes.

Neural crest populations arise from the neural folds as primary neurulation proceeds and simultaneously progresses rostrally and caudally. Crest cells migrate from the neural folds of the brain prior to tube closure. Caudally, from approximately somite 29, secondary neurulation processes produce the most caudal neural crest. Two distinct populations of neural crest cells are formed: a neuronal population produced throughout the brain and spinal cord which gives rise to sensory and autonomic neurones and glia, and a non-neuronal mesenchymal population which arises only from the brain (Figs 24.9 and 24.10). Melanocytes develop from a subpopulation of neural crest cells derived from both the head and trunk. They form one of the three pigment cell types (the others being retinal pigment epithelium and the pigment cells of the pineal organ, which both originate from the diencephalon).
Fig. 24.9 A. Fate map along the neural crest of the presumptive territories which yield the ectomesenchyme, the sensory, parasympathetic and sympathetic ganglia and neural crest derived mesenchyme in normal development. B. Developmental potentials for the same cell types. If neural crest cells from any level of the neural axis are implanted into the appropriate sites of a host embryo, they can give rise to almost all the cell types forming the various kinds of PNS ganglia. This is not true for the neural crest derived mesenchyme whose precursors are confined to the cephalic area of the crest down to the level of somite 5. S, somite.
In the trunk the migration patterns of neural crest cells is channelled by the somites. As the crest cells move laterally and ventrally they can pass between the somites and within the rostral sclerotomal half of each somite, but they cannot penetrate the caudal moiety of the sclerotomal mesenchyme. Thus the segmental distribution of the spinal and sympathetic ganglia is imposed on the neural crest cells by a prepattern that exists within the somitic paraxial mesenchyme (Fig. 24.11). The origin of the cranial-caudal patterning of the ventral neural crest cells is not clear.
Rostral to the otic vesicle, neural crest cells arise from specific regions of the brain. Early in development, a number of transverse subdivisions perpendicular to the long axis of the brain can be seen within the rhombencephalon, dividing it into segments termed rhombomeres (Müller & O'Rahilly 1997). Eight main rhombomeres extend from the midbrain–hindbrain boundary rostrally to the spinal cord caudally (Fig. 24.2). Rhombomeres 8 and 7 give rise to neural crest cells which migrate into the fourth and sixth pharyngeal arches; rhombomere 6 crest cells invade pharyngeal arch three. Rhombomere 4 crest cells migrate into arch 2, whereas rhombomeres 5 and 3 give rise to a very small number of neural crest cells which migrate rostrally and caudally to enter the adjacent even-numbered neighbours. Rhombomeres 1 and 2 produce crest cells which invade the first pharyngeal arch. In each rhombomere, mesenchymal populations and the sensory and autonomic ganglia are formed from the crest cells (see Fig. 12.4).

Further rostrally, neural crest from the mesencephalon migrates into the first arch maxillary and mandibular processes. Crest cells are produced from the diencephalon up to the level of the epiphysis. Neural crest cells which are produced from this rostral portion of the brain contribute mesenchymal populations to the frontonasal process. The most rostral prosencephalic neural fold does not give rise to neural crest.
ECTODERMAL PLACODES

Prior to neural tube closure, the elevating neural folds contain two distinctive neuronal populations. The larger population of neural crest cells migrates from the neural epithelium prior to neural tube fusion. A smaller population of neuroepithelial cells becomes incorporated into the surface ectoderm after neural tube closure. These areas of neuroepithelium within the surface ectoderm have been termed ectodermal placodes. Although the majority of the ectodermal placodes form nervous tissue, non-neurogenic placodes also occur (Begbie & Graham 2001). After an appropriate inductive stimulus, the placodes thicken and either generate migratory neuronal cells that will contribute to the cranial sensory ganglia, or the whole placodal region invaginates to form a vesicle beneath the remaining surface ectoderm. Neurogenic placodes undergo both processes. Paired non-neurogenic placodes invaginate to form the lens vesicles under the inductive influence of the optic vesicles (see Ch. 41).

The neural folds meet in the rostral midline adjacent to the buccopharyngeal membrane. This rostral neural fold does not generate neural crest but gives rise to the hypophysial placode, i.e. the future Rathke’s pouch, which remains within the surface ectoderm directly rostral to the buccopharyngeal membrane. The rostral neural fold also gives rise to the olfactory placodes, which remain as paired, laterally placed placodes, and to the epithelium of the nasal cavity (Fig. 24.10).

Further caudally, similar neurogenic placodes can be identified and divided into three categories, namely the epibranchial, otic and trigeminal placodes (Fig. 24.12). The epibranchial placodes appear in the surface ectoderm immediately dorsal to the area of pharyngeal (branchial) cleft formation. The first epibranchial placode is located at the level of the first pharyngeal groove and contributes cells to the distal (geniculate) ganglion of the facial nerve, the second and third epibranchial placodes contribute cells to the distal ganglia of the glossopharyngeal (petrosal) and vagus (nodose) nerves respectively. These placodes thicken and cells begin to detach from their epithelium soon after the pharyngeal pouches have contacted the overlying ectoderm. Concurrently the neural crest cells reach and move beyond these lateral extensions of the pharynx. Neurones migrate from the epibranchial placodes internally to the sites of ganglion formation, where they show signs of early differentiation into neurones, including the formation of neurites.
Fig. 24.12 Scheme of a human embryo of stage 13 (4 mm, 32 somites), rendered flat to eliminate the cerebral flexures. The cranial sensory ganglia and otocyst, derived from the epibranchial placodes are shown on the left. The levels of origin of the neural crest which contributes to the cranial sensory ganglia and mesenchymal populations in the head on the right is indicated. This arrangement may vary in other species. (Provided by Professor R O’Rahilly and Dr F Müller.)

The otic placodes, located lateral to the myelencephalon, invaginate to form otic vesicles from which the membranous labyrinth of the ear develops. Neurones of the vestibulocochlear nerve ganglia arise from neurones that bud off the ventromedial aspect of the otic cup, after which they can be distinguished in the acoustic and vestibular ganglia (see Ch. 38).
The profundal and maxillomandibular trigeminal placodes, which fuse in man to form a single entity, lie rostral of the otic placodes, alongside the mesencephalic–rhombencephalic junction. Prospective neuroblasts migrate from foci dispersed throughout the surface ectoderm lateral and ventrolateral to the caudal mesencephalon and metencephalon to contribute to the distal portions of the trigeminal ganglia.

**PITUITARY GLAND (HYPOPHYSIS CEREBRI)**

The hypophysis cerebri consists of the adenohypophysis and the neurohypophysis. Prior to neurulation the cell populations which give rise to these two portions of the pituitary gland are found next to each other within the rostral portion of the floor of the neural plate and the contiguous midline neural fold. As neurulation proceeds the future neurohypophysis remains within the floor of the prosencephalon. The cells of the future adenohypophysis are displaced into the surface ectoderm, where they form the hypophysial placode in close apposition and adherent to the overlying prosencephalon.

Neural crest mesenchyme later moves between the prosencephalon and surface ectoderm except at the region of the placode. Before rupture of the buccopharyngeal membrane, proliferation of the periplacodal mesenchyme means that the placode forms the roof and walls of a saccular depression. This hypophysial recess (pouch of Rathke, Figs 24.13 and 24.14) is the rudiment of the adenohypophysis. It lies immediately ventral to the dorsal border of the buccopharyngeal membrane, extending in front of the rostral tip of the notochord, and retaining contact with the ventral surface of the prosencephalon. It is constricted by continued proliferation of the surrounding mesenchyme to form a closed vesicle, but remains for a time connected to the ectoderm of the stomodeum by a solid cord of cells, which can be traced down the posterior edge of the nasal septum. Masses of epithelial cells form mainly on each side and in the ventral wall of the vesicle, and the development of the adenohypophysis progresses by the ingrowth of a mesenchymal stroma. Differentiation of epithelial cells into stem cells and three differentiating types is said to be apparent during the early months of fetal development. It has been suggested that different types of cells arise in succession, and that they may be derived in differing proportions from different parts of the hypophysial recess. A craniopharyngeal canal, which sometimes runs from the rostral part of the hypophysial fossa of the sphenoid to the exterior of the skull, is often said to mark the original position of the hypophysial recess. Traces of the stomodeal end of the recess are usually present at the junction of the septum
of the nose with the palate. Others have claimed that the craniopharyngeal canal itself is a secondary formation caused by the growth of blood vessels, and is quite unconnected with the stalk of the adenohypophysis.

Fig. 24.13 Scanning electron micrograph of the roof of the pharynx showing the invagination of placodal ectoderm to form the adenohypophysis (Rathke's pouch).

(Photograph by P Collins; printed by S Cox, Electron Microscopy Unit, Southampton General Hospital.)
A small endodermal diverticulum, named Seessel's pouch, projects towards the brain from the cranial end of the foregut, immediately caudal to the buccopharyngeal membrane. In some marsupials this pouch forms a part of the hypophysis, but in man it is not well defined and disappears entirely.

Just caudal to, but in contact with, the adenohypophysial recess, a hollow diverticulum elongates towards the stomodeum from the floor of the neural plate just caudal to the hypothalamus (Fig. 24.14B); this region of neural
outgrowth is the neurohypophysis. It forms an infundibular sac, the walls of which increase in thickness until the contained cavity is obliterated except at its upper end, where it persists as the infundibular recess of the third ventricle. The neurohypophysis becomes invested by the adenohypophysis, which extends dorsally on each side of it. The adenohypophysis gives off two processes from its ventral wall which grow along the infundibulum and fuse to surround it, coming into relation with the tuber cinereum and forming the tuberal portion of the hypophysis. The original cavity of Rathke's pouch remains first as a cleft, and later as scattered vesicles, and can be identified readily in sagittal sections through the mature gland. The dorsal wall of Rathke's pouch remains thin and fuses with the adjoining part of the neurohypophysis as the pars intermedia.

At birth the hypophysis is about one-sixth the weight of the adult gland: it increases in weight to become about one-half the weight of the adult gland at 7 years, and attains adult weight at puberty. Throughout postnatal life the gland appears larger in females, in both size and weight.
Glial cells which support neurones in the CNS and PNS are derived from three lineages, namely, neuroectoderm, neural crest and angioblastic mesenchyme. In the CNS, cells of the proliferating ventricular zone give rise to astrocytes and oligodendrocytes. After the proliferative phase the cells remaining at the ventricular surface differentiate into ependymal cells, which are specialized in many regions of the ventricular system as circumventricular organs. In the PNS, neural crest cells produce Schwann cells and astrocyte-like support cells in the enteric nervous system. Angioblastic mesenchyme gives rise to a variety of blood cell types including circulating monocytes which infiltrate the brain as microglial cells later in development.

The ventricular zone lining the early central canal of the spinal cord and the cavities of the brain gives rise to neurones and glial cells (Figs 24.4 and 24.5). One specialized form of glial cell is the radial glial cell, whose radial processes extend both outwards to form the outer limiting membrane deep to the pia mater, and inwards, to form the inner limiting membrane around the central cavity. The geometry of these cells may provide contact guidance paths for cell migrations, both neuronic and glioblastic. A secondary radial glial scaffold is formed in the late developing cerebellum and dentate gyrus and serves to translocate neurones, formed in secondary germinal centres, to their definitive adult locations. Radial glia eventually lose their connections with both inner and outer limiting membranes, except those persisting in the retina as Müller cells, in the cerebellum as Bergmann glia and in the hypothalamus as tanycytes. They can differentiate into neurones as well as astrocytes. They may partially clothe the somata of neighbouring developing neurones (between presumptive synaptic contacts), or similarly enwrap the intersynaptic surfaces of their neurites. Glial processes may expand around intraneural capillaries as perivascular end-feet. Other glioblasts retain an attachment (or form new expansions) to the pia mater, the innermost stratum of the meninges, as pial end-feet. Glioblasts also line the central canal and cavities of the brain as generalized or specialized ependymal cells, but lose their peripheral attachments. In some situations, as in the anterior median fissure of the spinal cord, ependymal cells retain their attachments to both the inner and outer limiting membranes. Thus, glia function as perineuronal satellites, and provide cellular channels interconnecting extracerebral and intraventricular cerebrospinal fluid, the cerebral vascular bed, the intercellular crevices of the neuropil and the cytoplasm of all neural cell varieties.

Microglia appear in the CNS after it has been penetrated by blood vessels and invade it in large numbers from certain restricted regions, whence they spread in what have picturesquely been called ‘fountains of microglia’, to extend deeply among the nervous elements.
MECHANISMS OF NEURAL DEVELOPMENT

For more than a century the mechanisms that operate during the development of the nervous system have been studied experimentally. While much has been established, answers to many fundamental questions still remain obscure. In recent years, significant advances in our understanding of the development of vertebrates have come from work on amphibian, chicken, mouse and fish embryos, using a combination of genetic, embryological, biochemical and molecular techniques to elucidate the mechanisms that regulate the behaviour of early neural populations.

The CNS has a fundamental structure of layers and cells, which are all derived from a pluripotent neuroepithelium. Developing neurones produce axons which traverse great distances to reach their target organs. Within the CNS, they form myriad connections with other neurons in response to locally secreted cues.

HISTOGENESIS OF THE NEURAL TUBE

The wall of the early neural tube consists of an internal ventricular zone (sometimes termed the germinal matrix) abutting the central lumen. It contains the nucleated parts of the pseudostratified columnar neuroepithelial cells and rounded cells undergoing mitosis. The early ventricular zone also contains a population of radial glial cells whose processes pass from the ventricular surface to the pial surface, thus forming the internal and external glia limitans (glial limiting membrane). As development proceeds the early pseudostratified epithelium proliferates and an outer layer, the marginal zone, devoid of nuclei but containing the external cytoplasmic processes of cells, is delineated. Subsequently a middle, mantle layer (intermediate zone) forms as the newly formed neurones migrate ventriculofugally from the ventricular zone (see Fig. 24.5).

Most CNS cells are produced in the proliferative zone adjacent to the future ventricular system, and in some regions this area is the only actively mitotic zone. According to the monophyletic theory of neurogenesis it is assumed to produce all cell types. The early neural epithelium, including the deeply placed ventricular mitotic zone, consists of a homogeneous population of pluripotent cells whose varying appearances reflect different phases in a proliferative cycle. The ventricular zone is considered to be populated by a single basic type of progenitor cell and to exhibit three phases. The cells show an ‘elevator movement’ as they pass through a complete mitotic cycle, progressively approaching and then receding from the internal limiting membrane (Fig. 24.15). DNA replication occurs while the cells are extended and their nuclei approach the pial surface; they then enter a premitotic resting period while the cells shorten and their nuclei pass back towards the ventricular surface. The cells now become rounded close to the internal limiting membrane and undergo mitosis. They then elongate and their nuclei move towards the outer edge during the postmitotic resting period, after which DNA synthesis commences once more and the cycle is repeated. The cells so formed may then either start another proliferative cycle or migrate outwards (i.e. radially) and differentiate into neurones as they approach and enter the adjacent stratum. This differentiation may be initiated as they pass outwards during the postmitotic resting period. The proliferative cycle continues with the production of clones of neurones and glioblasts. This sequence of events has been called inter-kinetic nuclear migration: it eventually declines. At the last division two postmitotic daughter cells are produced and they differentiate at the ventricular surface into
ependyma.

The progeny of some of these divisions move away from the ventricular zone to form an intermediate zone of neurones. The early spinal cord and much of the brain stem shows only these three main layers, i.e. ventricular, intermediate and marginal zones. However, in the telencephalon the region of cellular proliferation extends deeper than the ventricular zone where the escalator movement of interkinetic migration is seen, and a subventricular zone appears between the ventricular and intermediate layers (Fig. 24.15). Here cells continue to multiply to provide further generations of neurones and glia which subsequently migrate into the intermediate and marginal zones. In some regions of the nervous system (e.g. the cerebellar cortex) some mitotic subventricular stem cells migrate across the entire neural wall to form a subpial population, and establish a new zone of cell division and differentiation. Many cells formed in this site remain subpial in position, but others migrate back towards the ventricle through the developing nervous tissue, and finish their migrations in various definitive sites where they differentiate into neurones or macroglial cells. In the cerebral hemispheres, a zone termed the cortical plate is formed outside the intermediate zone by radially migrating cells from the ventricular zone. The most recently formed cells migrate to the outermost layers of the cortical plate, so that
earlier formed and migrating cells become subjacent to those migrating later. In the forebrain there is an additional transient stratum deep to the early cortical plate, the subplate zone.
Neurones come from three embryonic sources: CNS neurones originate from the pluripotential neural plate and tube, whereas ganglionic neurones originate from the neural crest and ectodermal placodes. The neural plate also provides ependymal and macroglial cells. Peripheral Schwann cells and chromaffin cells arise from the neural crest. The origins and lineages of cells in the nervous system have been determined experimentally by the use of autoradiography, microinjection or retroviral labelling of progenitor cells, and in cell culture.

During development, neurones are formed before glial cells. The timing of events differs in various parts of the CNS and between species. Most neurones are formed prenatally in mammals but some postnatal neurogenesis does occur, e.g. the small granular cells of the cerebellum, olfactory bulb and hippocampus, and neurones of the cerebral cortex. Gliogenesis continues after birth in periventricular and other sites. Autoradiographic studies have shown that different classes of neurones develop at specific times. Large neurones such as principal projection neurones tend to differentiate before small ones such as local circuit neurones. However, their subsequent migration appears to be independent of the times of their initial formation. Neurones can migrate extensively through populations of maturing, relatively static cells, to reach their destination, e.g. cerebellar granule cells pass through a layer of Purkinje cells en route from the external pial layer to their final central position. Later, the final form of their projections, cell volume and indeed their continuing survival, depend on the establishment of patterns of functional connection.

Initially immature neurones are rotund or fusiform. Their cytoplasm contains a prominent Golgi apparatus, many lysosomes, glycogen and numerous unattached ribosomes. As maturation proceeds, cells send out fine cytoplasmic processes which contain neurofilaments, microtubules and other structures, often including centrioles at their bases where microtubules form. Internally, endoplasmic reticulum cisternae appear and attached ribosomes and mitochondria proliferate, whereas the glycogen content progressively diminishes. One process becomes the axon and other processes establish a dendritic tree. Axonal growth, studied in tissue culture, may be as much as 1 mm per day.

**Growth cones**

Ramón y Cajal (1890) was the first to recognize that the expanded end of an axon, the growth cone, is the principal sensory organ of the neurone. Classically, the growth cone is described as an expanded region that is constantly active, changing shape, extending and withdrawing small filopodia and lamellipodia that apparently ‘explore’ the local environment for a suitable
surface along which extension may occur. These processes are stabilized in one direction, determining the direction of future growth, and following consolidation of the growth cone, the exploratory behaviour recommences. This continuous cycle resembles the behaviour at the leading edge of migratory cells such as fibroblasts and neutrophils. The molecular basis of this behaviour is the transmission of signals external to the growth cone via cell surface receptors to the scaffolding of microtubules and neurofilaments within the axon. Growing neuroblasts have a cortex rich in actin associated with the plasma membrane, and a core of centrally located micro-tubules and sometimes neurofilaments. The assembly of these components, along with the synthesis of new membrane, occurs in segments distal to the cell body and behind the growth cone, though some assembly of microtubules may take place near the cell body.

The driving force of growth cone extension is uncertain. One possible mechanism is that tension applied to objects by the leading edge of the growth cone is mediated by actin, and that local accumulations of F-actin redirect the extension of microtubules. Under some culture conditions, growth cones can develop mechanical tension, pulling against other axons or the substratum to which they are attached. Possibly, tension in the growth cone acts as a messenger to mediate the assembly of cytoskeletal components. Adhesion to the substratum appears to be important for consolidation of the growth cone and elaboration of the cytoskeleton in that direction.

During development, the growing axons of neuroblasts navigate with precision over considerable distances, often pursuing complex courses to reach their targets. Eventually they make functional contact with their appropriate end organs (neuromuscular endings, secreto-motor terminals, sensory corpuscles or synapses with other neurones). During the outgrowth of axonal processes the earliest nerve fibres are known to traverse appreciable distances over an apparently virgin landscape, often occupied by loose mesenchyme. A central problem for neurobiologists, therefore, has been understanding the mechanisms of axon guidance (Gordon-Weeks 2000). Axon guidance is thought to involve short-range, local guidance cues and long-range diffusible cues, any of which can be either attractive and permissive for growth, or repellent and hence inhibitory. Short-range cues require factors which are displayed on cell surfaces or in the extracellular matrix, e.g. axon extension requires a permissive, physical substrate, the molecules of which are actively recognized by the growth cone. They also require negative cues which inhibit the progress of the growth cone. Long-range cues come from gradients of specific factors diffusing from distant targets, which cause neurones to turn their axons towards the source of the attractive signal. The evidence for this has come from in vitro co-culture studies. The floor plate of the developing spinal cord exerts a chemotropic effect on commissural axons that later cross it, whereas there is chemorepulsion of developing motor axons from the floor plate. These forces
are thought to act \textit{in vivo} in concert in a dynamic process to ensure the correct passage of axons to their final destinations and to mediate their correct bundling together en route.

**Dendritic tree**

Once growth cones have arrived in their general target area, they then have to form terminals and synapses. In recent years, much emphasis has been placed on the idea that patterns of connectivity depend on the death of inappropriate cells. Programmed cell death or apoptosis occurs during the period of synaptogenesis if neurones fail to acquire sufficient amounts of specific neurotrophic factors. Coincident firing of neighbouring neurones that have found the appropriate target region might be involved in eliciting release of factor(s), thus reinforcing correct connections. Such mechanisms may explain the numerical correspondence between neurones in a motor pool and the muscle fibres innervated. On a subtler level, pruning of collaterals may give rise to mature neuronal architecture. The projections of pyramidal neurones from the motor and visual cortex, for example, start out with similar architecture: the mature repertoire of targets is produced by the pruning of collaterals leading to loss of projections to some targets.

The final growth of dendritic trees is also influenced by patterns of afferent connections and their activity. If deprived of afferents experimentally, dendrites fail to develop fully and, after a critical period, may become permanently affected even if functional inputs are restored, e.g. in the visual systems of young animals which have been visually deprived. This is analogous to the results of untreated amblyopia in infants. Metabolic factors also affect the final branching patterns of dendrites, e.g. thyroid deficiency in perinatal rats results in a small size and restricted branching of cortical neurones. This may be analogous to the mental retardation of cretinism.

Once established, dendritic trees appear remarkably stable and partial deafferentation affects only dendritic spines or similar small details. As development proceeds plasticity is lost, and soon after birth a neuron is a stable structure with a reduced rate of growth.

**Neurotrophins**

If neurones lose all afferent connections or are totally deprived of sensory input, there is atrophy of much of the dendritic tree and even the whole soma. Different regions of the nervous system vary quantitatively in their response to such anterograde transneuronal degeneration. Similar effects occur in retrograde transneuronal degeneration. Thus neurones are dependent on peripheral structures for their survival. Loss of muscles or sensory nerve endings, e.g. in the developing limb, will result in reduction in numbers of motor and sensory neurones. Specific factors which these target organs
produce, such as the neurotrophins, are taken into nerve endings and transported back to the neuronal somata: they are necessary for the survival of many types of neurone during early development, and for the growth of their axons and dendrites, and also promote the synthesis of neurotransmitters and enzymes.

The neurotrophins, nerve growth factor (NGF), brain derived neurotrophic factor (BDNF), neurotrophin 3 (NT-3) and NT-4/5 exert their survival effects selectively on particular subsets of neurones. NGF is specific to sensory ganglion cells from the neural crest, sympathetic postganglionic neurones and basal forebrain cholinergic neurones. BDNF promotes the survival of retinal ganglion cells, motor neurones, and some placode-derived neurones, such as those of the nodose ganglion, that are unresponsive to NGF. NT-3 has effects on motor neurones, limb proprioceptive neurones and both placode and neural crest-derived sensory neurones. Other growth factors found to influence the growth and survival of neural cells include the fibroblast growth factors (FGFs) and ciliary neurotrophic factor (CNTF), all of which are unrelated in sequence to the NGF family. Members of the FGF family support the survival of embryonic neurones from many regions of the CNS. CNTF may control the proliferation and differentiation of sympathetic ganglion cells and astrocytes.

Each of the neurotrophins binds specifically to certain receptors on the cell surface. The receptor termed p75\textsuperscript{NTR} binds all the neurotrophins with similar affinity. By contrast, members of the family of receptor tyrosine kinases (Trks) bind with higher affinity and display binding preferences for particular neurotrophins. However, the presence of a Trk receptor seems to be required for p75\textsuperscript{NTR} function.

Nervous tissue influences the metabolism of its target tissues. If during development a nerve fails to connect with its muscle, both degenerate. If the innervation of slow (red) or fast (white) skeletal muscle is exchanged, the muscles change structure and properties to reflect the new innervation, indicating that the nerve determines muscle type and not vice versa.
INDUCTION AND PATTERNING OF THE BRAIN AND SPINAL CORD

The generation of neural tissue involves an inductive signal from the underlying chordamesoderm (notochord), termed the ‘organizer’. The observation by Spemann in 1925 that, in intact amphibian embryos, the presence of an organizer caused ectodermal cells to form nervous tissue, whereas in its absence they formed epidermis, led to the discovery of neural induction. However, experiments performed much later in the century revealed that when ectodermal cells were dissociated they also gave rise to neural tissue. The paradox was resolved by the finding that intact ectodermal tissue is prevented from becoming neural by an inhibitory signal(s) that is diluted out when cells are dissociated. Many lines of evidence now indicate that this inhibitory signal is mediated by members of a family of secreted proteins, the bone morphogenetic proteins (BMP). These molecules are found throughout ectodermal tissue during early development, and their inhibitory effect is antagonized by several neural inducers which are present within the organizer, i.e. noggin, chordin and follistatin. Each of these factors is capable of blocking BMP signalling, in some cases by preventing it from binding to its receptor(s).

The regional pattern of the nervous system is induced before and during neural tube closure. Early concepts about regional patterning envisaged that regionalization within mesenchymal populations which transmit inductive signals to the ectoderm impose a similar mosaic of positional values on the overlying neural plate. For example, transplantation of caudal mesenchyme beneath the neural plate in Amphibia induced spinal cord, whereas rostral mesenchyme induced brain, as assessed by the morphology of the neuroepithelial vesicles. However, later work indicated a more complex scenario in which organizer grafts from early embryos induced mainly head structures, while later grafts induced mainly trunk structures. Subsequent molecular data have tended to support a model in which neural-inducing factors released by the organizer such as noggin, chordin and follistatin, neuralize the ectoderm and promote a mainly rostral neural identity. Later secreted signals then act to caudalize this rostral neural tissue, setting up an entire array of axial values along the neural tube. Candidates for these later, caudalizing, signals have been shown to be retinoic acid, fibroblast growth factors and the WNT secreted proteins, which are present in the paraxial mesenchyme and later in its derivatives, the somites. This combination of signals does not seem to be sufficient to produce the most rostral, forebrain structures. Other secreted proteins resident in the rostralmost part of the earliest ingressing axial populations of endoderm and mesenchyme are also capable of inducing markers of forebrain identity from ectodermal cells (Withington, Beddington & Cooke 2001).

As the neural tube grows and is modified in shape, a number of mechanisms refine the crude rostrocaudal pattern which has been imposed during neurulation. Molecules which diffuse from tissues adjacent to the neural tube such as the somites have patterning influences. The neural tube possesses a number of intrinsic signalling centres, such as the midbrain–hindbrain boundary, which produce diffusible molecules capable of influencing tissue development at a distance. In this way extrinsic and intrinsic factors serve to subdivide the neural tube into a number of fairly large domains, on which local influences can then act.
Domains are distinguished by their expression of particular transcription factors, which in many cases have been causally related to the development of particular regions. Examples of such genes are the Hox family which are expressed in the spinal cord and hindbrain, and the Dlx, Emx and Otx families of genes which are expressed in various regions of the forebrain. All of these are developmental control genes which lie high up in the hierarchy, and are capable of initiating cascades of expression of other genes to create a more fine-grained pattern of cellular differentiation. In contrast to the aforementioned secreted molecules, these genes encode proteins which are retained in the cell nucleus, and so can act on DNA to induce or repress further gene expression.

**Segmentation in the neural tube**

The early neural tube is visibly divided into segments, termed neuromeres, by shallow transverse folds which extend perpendicular to its long axis. Primary neuromeres can be identified at stage 9, and 16 secondary neuromeres are present at stage 14. They are especially noted in the rhombencephalon, where they are termed rhombomeres; they have now been shown to constitute crucial units of pattern formation. Domains of expression of developmental control genes abut rhombomere boundaries; single cell labelling experiments have revealed that cells within rhombomeres form segregated non-mixing populations (Fig. 24.16). The neural crest also shows intrinsic segmentation in the rhombencephalon, and is segregated into streams at its point of origin in the dorsal neural tube. This may represent a mechanism whereby morphogenetic specification of the premigratory neural crest cells is conveyed to the pharyngeal arches (see Fig. 12.4). Although these segmental units lose their morphological prominence with subsequent development, they represent the fundamental ground plan of this part of the neuraxis, creating a series of semi-autonomous units within which local variations in patterning can then develop. The consequences of early segmentation for events later in development, such as the formation of definitive neuronal nuclei within the brain stem, and of peripheral axonal projections remain to be explored.
Fig. 24.16  *Hox* gene expression domains in the branchiorhombomeric area in the mouse embryo at E9.5. The arrows indicate neural crest cells migrating from the rhombencephalon and midbrain. At the former level, they are shaded to indicate which *Hox* genes they express. The same combination of *Hox* genes is expressed in the rhombomeres and in the superficial ectoderm of the pharyngeal arches at the corresponding rostrocaudal levels. The four *Hox* clusters are represented below.

(Modified by permission from the Annual Review of Cell and Developmental Biology, Volume 8, 1992 by Annual Reviews www.annualreviews.org.)

Other brain regions are not segmented in quite the same way as the hindbrain. However, morphological boundaries, domains of cell lineage restriction and of cell mixing, and regions of gene expression that abut sharp boundaries, are found in the diencephalon and telencephalon. It is thus likely that compartmentation of cell groups with some, if not all, the features of rhombomeres plays an important role in the formation of various brain regions.

The significance of intrinsic segmentation in the hindbrain is underlined by the absence of overt segmentation of the adjacent paraxial mesenchyme. There is no firm evidence for intrinsic segmentation in the spinal cord. Instead, segmentation of the neural crest, motor axons, and thus eventually the spinal nerves, is dependent on the segmentation of the neighbouring somites. Both neural crest cell migration and motor axon outgrowth occur through only the rostral and not the caudal sclerotome of each somite, so that dorsal root ganglia form only at intervals. The caudal sclerotome possesses inhibitory properties that deter neural crest cells and motor axons from entering. This illustrates the general principle that the nervous system is closely interlocked, in terms of morphogenesis, with the ‘periphery’, i.e. surrounding non-nervous structures, and each is dependent upon the other for its effective structural and functional maturation.
Genes such as the Hox and Pax gene families, which encode transcription factor proteins, show intriguing expression patterns within the nervous system. Genes of the Hox-b cluster, for example, are expressed throughout the caudal neural tube, and up to discrete limits in the hindbrain that coincide with rhombomere boundaries. The ordering of these genes within a cluster on the chromosome (5′-3′) is the same as the caudal to rostral limits of expression of consecutive genes. This characteristic pattern is surprisingly similar in fish, frogs, birds and mammals. Hox genes play a role in patterning not only of the neural tube but also of much of the head region, consistent with their expression in neural crest cells, and within the pharyngeal arches. Disruption of Hox a-3 gene in mice mimics DiGeorge's syndrome, a congenital human disorder characterized by the absence (or near absence) of the thymus, parathyroid and thyroid glands, by the hypotrophy of the walls of the arteries derived from the aortic arches, and by subsequent conotruncal cardiac malformations. Some Pax genes are expressed in different dorsoventral domains within the neural tube. Pax-3 is expressed in the alar lamina, including the neural crest, while Pax-6 is expressed in the intermediate plate. The Pax-3 gene has the same chromosomal localization as the mouse mutation Splotch and the affected locus in the human Waardenburg's syndrome, both of which are characterized by neural crest disturbances with pigmentation disorders and occasional neural tube defects. Both Hox and Pax genes have restricted expression patterns with respect to the rostrocaudal and the dorsoventral axes of the neural tube, consistent with roles in positional specification. (For reviews of the expression patterns of these genes see Krumlauf et al 1993.)

While craniocaudal positional values are probably conferred on the neuroepithelium at the neural plate or early neural tube stage, dorsoventral positional values may become fixed later. The development of the dorsoventral axis is heavily influenced by the presence of the underlying notochord. The notochord induces the ventral midline of the neural tube, the floor plate. This specialized region consists of a strip of non-neural cells with distinctive adhesive and functional properties. Notochord and floor plate together participate in inducing the differentiation of the motor columns. Motor neurone differentiation occurs early, giving some grounds for the idea of a ventral to dorsal wave of differentiation. The notochord/floor plate complex may also be responsible for allotting the values of more dorsal cell types within the tube (Fig. 24.7). For example, the dorsal domain of expression of Pax-3 extends more ventrally in embryos experimentally deprived of notochord and floor plate, while grafting an extra notochord adjacent to the dorsal neural tube leads to a repression of Pax-3 expression.
PERIPHERAL NERVOUS SYSTEM

SOMATIC NERVES

Spinal nerves

Each spinal nerve is connected to the spinal cord by a ventral root and a dorsal root (Fig. 24.17). The fibres of the ventral roots grow out from cell bodies in the anterior and lateral parts of the intermediate zone. These pass through the overlying marginal zone and external limiting membrane. Some enter the myotomes of the somites, and some penetrate the somites, reaching the adjacent somatopleure, and in both sites they ultimately form the α-, β- and γ-efferents. At appropriate levels these are accompanied by the outgrowing axons of preganglionic sympathetic neuroblasts (segments T1–L2), or preganglionic parasympathetic neuroblasts (S2–S4).

The fibres of the dorsal roots extend from cell somata in dorsal root ganglia (DRG) into the spinal cord and also extend into the periphery. Neural crest cells are produced continuously along the length of the spinal cord, but gangliogenic cells migrate only into the rostral part of each somitic sclerotome where they condense and proliferate to form a bilateral series of oval-shaped primordial spinal ganglia (dorsal root ganglia) (Fig. 24.11). Negative factors in the caudal sclerotome deter neural crest from entering. The rostral sclerotome has a mitogenic effect on the crest cells that settle within it. From the ventral region of each ganglion a small part separates to form sympathochromaffin cells, while the remainder becomes a definitive spinal ganglion (dorsal root ganglion). The spinal ganglia are arranged symmetrically at the sides of the neural tube and, except in the caudal region, are equal in number to the somites. The cells of the ganglia, like the cells of the intermediate zone of the early neural tube, are glial and neuronal precursors. The glial precursors develop into satellite cells (which become closely applied to the ganglionic nerve cell somata), Schwann cells, and possibly other cells. The neuroblasts, at first round or oval, soon become fusiform, and their extremities gradually elongate into central and peripheral processes. The central processes grow into the neural tube as the fibres of dorsal nerve roots, while the peripheral processes grow ventrolaterally to mingle with the fibres of the ventral...
root, thus forming a mixed spinal nerve. As development proceeds the original bipolar form of the cells in the spinal ganglia changes and the two processes become approximated until they ultimately arise from a single stem to form a unipolar cell. The bipolar form is retained in the ganglion of the vestibulocochlear nerve.

Cranial nerves

Cranial nerves may contain motor, sensory or both types of fibres. With the exception of the olfactory and optic nerves, the cranial nerves develop in a manner similar in some respects to components of the spinal nerves. The somata of motor neuroblasts originate within the neuroepithelium, while those of sensory neuroblasts are derived from the neural crest with the addition in the head of contributions from ectodermal placodes (Fig. 24.18; see Fig. 12.4).

Fig. 24.18 The brain and cranial nerves of a human embryo, 10.2 mm long. Note the derivation of the ganglia associated with the trigeminal, facial, vestibulocochlear, glossopharyngeal, vagus and spinal accessory nerves.

The motor fibres of the cranial nerves which project to striated muscle are the axons of cells originating in the basal plate of the midbrain and hindbrain. The functional and morphological distinction between the neurones within these various nerves is based on the types of muscle innervated. In the trunk, the motor roots of the spinal nerves all emerge from the spinal cord close to the ventral midline to supply the muscles derived from the somites.

In the head the motor outflow is traditionally segregated into two pathways (Figs 24.3B and 24.18). General somatic efferent neurones exit ventrally in a similar manner to those of the spinal cord. Thus the oculomotor, trochlear, abducens and hypoglossal nerves parallel the organization of the somatic motor neurones in the spinal cord. The second motor component, special branchial efferent, consists of the motor parts of the trigeminal, facial, glossopharyngeal and vagus nerves which supply the pharyngeal (branchial) arches, and the accessory nerve. These nerves all have nerve exit points more dorsally placed than the somatic motor system.
The cranial nerves also contain general visceral efferent neurones (parasympathetic preganglionic) which travel in the oculomotor, facial, glossopharyngeal and vagus nerves and leave the hindbrain via the same exit points as the special branchial efferent fibres. All three categories of motor neurones probably originate from the same region of the basal plate, adjacent to the floor plate. The definitive arrangement of nuclei reflects the differential migration of neuronal somata. It is not known whether all these cell types share a common precursor within the rhombencephalon, however, in the spinal cord somatic motor and preganglionic autonomic neurones are linearly related.

These motor neurone types have been designated according to the types of muscles or structures they innervate. General somatic efferent nerves supply striated muscle derived from the cranial (occipital) somites and prechordal mesenchyme. Myogenic cells from the ventrolateral edge of the epithelial plate of occipital somites give rise to the intrinsic muscles of the tongue, while the prechordal mesenchyme gives rise to the extrinsic ocular muscles. Special branchial efferent nerves supply the striated muscles developing within the pharyngeal (branchial) arches (see Fig. 12.4) which are derived from parachordal mesenchyme between the occipital somites and the prechordal mesenchyme. All the voluntary muscles of the head originate from axial (prechordal) or paraxial mesenchyme which renders the distinction between somatic efferent supply and branchial efferent supply somewhat artificial. However, the obviously special nature of the arch musculature, its patterning by the neural crest cells, its particularly rich innervation for both voluntary and reflex activity, and the different origins from the basal plate of the branchial efferent nerves compared to the somatic efferent nerves, make the retention of a distinction between the two of some value.

General visceral efferent neurones (parasympathetic preganglionic) innervate glands of the head, the sphincter pupillae and ciliary muscles, and the thoracic and abdominal viscera.

The cranial sensory ganglia are derived in part from the neural crest, and in part from cells of the ectodermal placodes (Figs 24.12 and 24.18). Generally, neurones distal to the brain are derived from placodes while proximal ones are derived from the neural crest (Fig. 24.18). Supporting cells of all sensory ganglia arise from the neural crest. The most rostral sensory ganglion, the trigeminal, contains both neural crest and placode-derived neurones that mediate general somatic afferent functions. In the case of more caudal cranial nerves (the facial, glossopharyngeal and vagus), the same applies, but the two cell populations form separate ganglia in the case of each nerve. The proximal series of ganglia is neural crest derived (forming the proximal ganglion of the facial nerve, the superior ganglion of the glossopharyngeal nerve and the jugular ganglion of the vagus) while the distal series is derived from placodal cells (forming the geniculate ganglion of the facial nerve, the petrosal ganglion of the glossopharyngeal nerve and the nodose ganglion of the vagus). These ganglia contain neurones that mediate special, general visceral and somatic afferent functions. The vestibular ganglion contains both crest and placodal cells and the acoustic ganglion contains only placodal neurones: the axons from these cells are special somatic afferents and they all travel in the vestibulocochlear nerve.

The neurones and supporting cells of the cranial autonomic ganglia in the head and the trunk originate from neural crest cells. Caudal to the vagal ganglion, the occipital region of the neural crest is concerned with the ‘ganglia’ of the accessory and
hypoglossal nerves. Rudimentary ganglion cells may occur along the hypoglossal nerve in the human embryo, but they subsequently regress. Ganglion cells are found on the developing spinal root of the accessory nerve and are believed to persist in the adult. The central processes of the cells of these various ganglia, where they persist, enter the alar lamina of the hindbrain. Their peripheral processes join the efferent components of the nerve to be distributed to the various tissues innervated. Some incoming fibres from the facial, glossopharyngeal and vagus nerves collect to form an oval bundle, the tractus solitarius, on the lateral aspect of the myelencephalon. This bundle is the homologue of the oval bundle of the spinal cord, but in the hindbrain it becomes more deeply placed by the overgrowth, folding and subsequent fusion of tissue derived from the rhombic lip on the external aspect of the bundle.
AUTONOMIC NERVOUS SYSTEM

Autonomic nerves, apart from the preganglionic motor axons arising from the CNS, are formed by the neural crest. The autonomic nervous system includes the sympathetic and parasympathetic neurones in the peripheral ganglia and their accompanying glia, the enteric nervous system and glia, and the suprarenal medulla.

In the trunk at neurulation, neural crest cells migrate from the neural epithelium to lie transitorily on the fused neural tube. Thereafter crest cells migrate laterally and then ventrally to their respective destinations (Fig. 24.11). Within the head the neural crest cells migrate prior to neural fusion, producing a vast mesenchymal population as well as autonomic neurones.

The four major regions of neural crest cell distribution to the autonomic nervous system are cranial, vagal, trunk and lumbosacral. The cranial neural crest gives rise to the cranial parasympathetic ganglia, whereas the vagal neural crest gives rise to the thoracic parasympathetic ganglia. The trunk neural crest gives rise to the sympathetic ganglia, mainly the paravertebral ganglia, and suprarenomedullary cells. This category is often referred to as the sympathosuprarenal lineage.

Neurones of the enteric nervous system are described as arising from the vagal crest, i.e. neural crest derived from somite levels 1–7, and the sacral crest, caudal to the 28th somite. At all of these levels the crest cells also differentiate into glial-like support cells alongside the neurones (Fig. 24.19).
Fig. 24.19 The derivatives of neural crest cells in the trunk. The fate of crest cells arising at particular somite levels is shown.

Parasympathetic ganglia

Neural crest cells migrate from the region of the mesencephalon and rhombencephalon prior to neural tube closure. From rostral to caudal, three populations of neural crest have been noted: cranial neural crest, cardiac neural crest and vagal neural crest. The migration of the sacral neural crest and the formation of the caudal parasympathetic ganglia have attracted little
Neural crest cells from the caudal third of the mesencephalon and the rostral metencephalon migrate along or close to the ophthalmic branch of the trigeminal nerve and give rise to the ciliary ganglion. Cells migrating from the nucleus of the oculomotor nerve may also contribute to the ganglion; a few scattered cells are always demonstrable in postnatal life along the course of this nerve. Preotic myelencephalic neural crest cells give rise to the pterygopalatine ganglion, which may also receive contributions from the ganglia of the trigeminal and facial nerves. The otic and submandibular ganglia are also derived from myelencephalic neural crest and may receive contributions from the glossopharyngeal and facial cranial nerves respectively (see Fig. 12.4).

Neural crest from the region located between the otic placode and the caudal limit of somite 3 has been termed cardiac neural crest. Cells derived from these levels migrate through pharyngeal arches 3, 4, and 6 where they provide, inter alia, support for the embryonic aortic arch arteries, cells of the aorticopulmonary septum and truncus arteriosus. Some of these neural crest cells also differentiate into the neural anlage of the parasympathetic ganglia of the heart. Sensory innervation of the heart is from the inferior ganglion of the vagus, which is derived from the nodose placodes. Neural crest cells migrating from the level of somites 1–7 are collectively termed vagal neural crest; they migrate to the gut along with sacral neural crest.

**Sympathetic ganglia**

Neural crest cells migrate ventrally within the body segments, penetrate the underlying somites and continue to the region of the future paravertebral and prevertebral plexuses, where they form the sympathetic chain of ganglia and the major ganglia around the ventral visceral branches of the abdominal aorta (Figs 24.11 and 24.19). Neural crest cells are induced to differentiate into sympathetic neurones by the dorsal aorta through the actions of the signaling molecules, Bmp-4 and Bmp-7.

There is cell specific recognition of postganglionic neurones and the growth cones of sympathetic preganglionic neurones. They meet during their growth, and this may be important in guidance to their appropriate target. The position of postganglionic neurones, and the exit point from the spinal cord of preganglionic neurones, may influence the types of synaptic connections made, and the affinity for particular postganglionic neurones. When a postganglionic neuroblast in place it extends axons and dendrites and synaptogenesis occurs. The earliest axonal outgrowths from the superior cervical ganglion occur at about stage 14: although the axon is the first cell process to appear, the position of the neurones does not apparently influence the appearance of the cell processes.
The local environment plays a major role in controlling the appropriate differentiation of the presumptive autonomic ganglion neurones. The identity of the factors responsible for subsequent adrenergic, cholinergic or peptidergic phenotype has yet to be elucidated: it has been proposed that fibronectin and basal lamina components initiate adrenergic phenotypic expression at the expense of melanocyte numbers. Cholinergic characteristics are acquired relatively early and the appropriate phenotypic expression may be promoted by cholinergic differentiation factor and ciliary neurotrophic factor.

Neuropeptides are expressed by autonomic neurones *in vitro* and may be stimulated by various target tissue factors in sympathetic and parasympathetic neurones. Some neuropeptides are expressed more intensely during early stages of ganglion formation.

**Enteric nervous system**

The enteric nervous system is different from the other components of the autonomic nervous system because it can mediate reflex activity independently of control by the brain and spinal cord. The number of enteric neurones that develop is believed to be of the same magnitude as the number of neurones in the spinal cord, whereas the number of preganglionic fibres that supply the intestine, and therefore modulate the enteric neurones, is much fewer.

The enteric nervous system is derived from the neural crest. The axial levels of crest origin are shown in Fig. 24.19. Premigratory neural crest cells are not prepatterned for specific axial levels, rather they attain their axial value as they leave the neuraxis. Once within the gut wall there is a regionally specific pattern of enteric ganglia formation which may be controlled by the local splanchnopleuric mesenchyme. Cranial neural crest from somite levels 1–7 contributes to the enteric nervous system, forming both neuroblasts and glial support cells.

The most caudal derivatives of neural crest cells, from the lumbosacral region, somites 28 onwards, form components of the pelvic plexus after migrating through the somites towards the level of the colon, rectum and cloaca. Initially the cells come to lie within the developing mesentery, then transiently between the layers of the differentiating muscularis externa, before finally forming a more substantial intramural plexus characteristic of the adult enteric nervous system.

Of the neural crest cells that colonize the bowel, some in the foregut may acquire the ability to migrate outwards and colonize the developing pancreas.

Hirschsprung's disease appears to result from a failure of neural crest cells to
colonize the gut wall appropriately. The condition is characterized by a
dilated segment of colon proximally and lack of peristalsis in the segment
distal to the dilatation. Infants with Hirschsprung's disease show delay in the
passage of meconium, constipation, vomiting and abdominal distension. In
humans, Hirschsprung's disease is often seen associated with other defects
of neural crest development, e.g. Waardenburg type II syndrome, which
includes deafness and facial clefts with megacolon.
**CHROMAFFIN CELLS**

Chromaffin cells are derived from the neural crest and found at numerous sites throughout the body. They are the classic chromaffin cells of the suprarenal medulla, bronchial neuroepithelial cells, dispersed epithelial endocrine cells of the gut (formerly known as argentaffin cells), carotid body cells, and the paraganglia.

The sympathetic ganglia, suprarenal medulla and chromaffin cells are all derived from the cells of the sympathosuprarenal lineage. In the suprarenal medulla these cells differentiate into a number of types consisting of small and intermediate-sized neuroblasts or sympathoblasts and larger, initially rounded phaeochromocytoblasts.

Large cells with pale nuclei, thought to be the progenitors of chromaffin cells, can be detected from 9 weeks in human fetuses, and clusters of small neurones are evident from 14 weeks.

Intermediate-sized neuroblasts differentiate into the typical multipolar postganglionic sympathetic neurones (which secrete noradrenaline at their terminals) of classic autonomic neuroanatomy. The smaller neuroblasts have been equated with the small intensely fluorescent (SIF) cells, types I and II, which store and secrete dopamine type I and are thought to function as true interneurones, synapsing with the principal postganglionic neurones. Type II probably operate as local neuroendocrine cells, secreting dopamine into the ganglionic microcirculation. Both types of SIF cells can modulate preganglionic/postganglionic synaptic transmission in the ganglionic neurones. The large cells differentiate into masses of columnar or polyhedral phaeochromocytes (classic chromaffin cells) which secrete either adrenaline (epinephrine) or noradrenaline (norepinephrine). These cell masses are termed paraganglia and may be situated near, on the surface of, or embedded in, the capsules of the ganglia of the sympathetic chain, or in some of the large autonomic plexuses. The largest members of the latter are the para-aortic bodies which lie along the sides of the abdominal aorta in relation to the inferior mesenteric artery. During childhood the para-aortic bodies and the paraganglia of the sympathetic chain partly degenerate and can no longer be isolated by gross dissection, but even in the adult, chromaffin tissue can still be recognized microscopically in these various sites. Both phaeochromocytes and SIF cells belong to the amine precursor uptake and decarboxylation (APUD) series of cells and are paraneuronal in nature.
CENTRAL NERVOUS SYSTEM

SPINAL CORD

In the future spinal cord the median roof plate (dorsal lamina) and floor plate (ventral lamina) of the neural tube do not participate in the cellular proliferation which occurs in the lateral walls and so remain thin. Their cells contribute largely to the formation of the ependyma.

The neuroblasts of the lateral walls of the tube are large and at first round or oval (apolar). Soon they develop processes at opposite poles and become bipolar neurons. However, one process is withdrawn and the neuroblast becomes unipolar, although this is not invariably so in the case of the spinal cord. Further differentiation leads to the development of dendritic processes and the cells become typical multipolar neurones. In the developing cord they occur in small clusters representing clones of neurones. The development of a longitudinal sulcus limitans on each side of the central canal of the cord divides the ventricular and intermediate zones in each lateral wall into a basal (ventrolateral) plate or lamina and an alar (dorsolateral) plate or lamina (Fig. 24.17). This separation indicates a fundamental functional difference. Neural precursors in the basal plate include the motor cells of the anterior (ventral) and lateral grey columns, while those of the alar plate exclusively form ‘interneurones’ (which possess both short and long axons), some of which receive the terminals of primary sensory neurones. Caudally the central canal of the cord ends as a fusiform dilatation, the terminal ventricle.

Anterior (ventral) grey column

The cells of the ventricular zone are closely packed at this stage and arranged in radial columns (Fig. 24.6). Their disposition may be determined in part by contact guidance along the earliest radial array of glial fibres which cross the full thickness of the early neuroepithelium. The cells of the intermediate zone are more loosely packed. They increase in number initially in the region of the basal plate. This enlargement outlines the anterior (ventral) column of the grey matter and causes a ventral projection on each side of the median plane: the floor plate remains at the bottom of the shallow groove so produced. As growth proceeds these enlargements, which are further increased by the development of the anterior funiculi (tracts of axons passing to and from the brain), encroach on the groove until it becomes converted into the slit-like anterior median fissure of the adult spinal cord (Fig. 24.17). The axons of some of the neuroblasts in the anterior grey column cross the marginal zone and emerge as bundles of ventral spinal nerve rootlets on the anterolateral aspect of the spinal cord. These constitute, eventually, both the α-efferents which establish motor end plates on extrafusal striated muscle fibres and the γ-efferents which innervate the contractile polar regions of the intrafusal muscle fibres of the muscle
spindles.

**Lateral grey column**

In the thoracic and upper lumbar regions some intermediate zone neuroblasts in the dorsal part of the basal plate outline a lateral column. Their axons join the emerging ventral nerve roots and pass as preganglionic fibres to the ganglia of the sympathetic trunk or related ganglia, the majority eventually myelinating to form white rami communicantes. The axons within the rami synapse on the autonomic ganglionic neurones, and axons of some of the latter pass as postganglionic fibres to innervate smooth muscle cells, adipose tissue or glandular cells. Other preganglionic sympathetic efferent axons pass to the cells of the suprarenal medulla. An autonomic lateral column is also laid down in the midsacral region. It gives origin to the preganglionic parasympathetic fibres which run in the pelvic splanchnic nerves.

The anterior region of each basal plate initially forms a continuous column of cells throughout the length of the developing cord. This soon develops into two columns (on each side): one is medially placed and concerned with innervation of axial musculature, and the other is laterally placed and innervates the limbs. At limb levels the lateral column enlarges enormously, but regresses at other levels.

Axons arising from ventral horn neurones, i.e. α-, β- and γ-efferent fibres, are accompanied at thoracic, upper lumbar and midsacral levels by preganglionic autonomic efferents from neuroblasts of the developing lateral horn. Numerous interneurones develop in these sites (including Renshaw cells): it is uncertain how many of these differentiate directly from ventrolateral lamina (basal plate) neuroblasts and how many migrate to their final positions from the dorsolateral lamina (alar plate).

In the human embryo, the definitive grouping of the ventral column cells, which characterizes the mature cord, occurs early, and by the 14th week (80 mm) all the major groups can be recognized. As the anterior and lateral grey columns assume their final form the germinal cells in the ventral part of the ventricular zone gradually stop dividing. The layer becomes reduced in thickness until ultimately it forms the single-layered ependyma which lines the ventral part of the central canal of the spinal cord.

**Posterior (dorsal) grey column**

The posterior (dorsal) column develops later; consequently the ventricular zone is for a time much thicker in the dorsolateral lamina (alar plate) than it is in the ventrolateral lamina (basal plate) (Fig. 24.6).

While the columns of grey matter are being defined, the dorsal region of the
central canal becomes narrow and slit-like, and its walls come into apposition and fuse with each other (Fig. 24.17). In this way the central canal becomes relatively reduced in size and somewhat triangular in outline.
